For austenitic stainless steels, Cr-Mn-N alloys generally have superior galling resistance, compared with the chromium-nickel alloys (Table 10, 11). Nickel is considered harmful to galling resistance, whereas silicon is considered beneficial. Thus, S20161 and S21800 have excellent resistance. Increasing the hardness of austenitic stainless alloys by cold drawing decreases galling resistance.

(a) Did not gall.

For the heat-treat-hardenable stainless steels, increasing hardness increases galling resistance. For martensitic PH stainless steels, increasing aging temperature may decrease galling resistance. For example, tests on S13880 and S17440 with similar hardness values (45 to 46 HRC) resulted in a much lower threshold galling stress (21 versus 69 MPa, or 3 versus 10 ksi) for S13800, which was aged at a higher temperature. Martensitic alloys, such as type 440C, tend to have heavy scoring damage, rather than galling.

Button-on-block test severity can be increased by increasing the number of button rotations against the block (Table 12). A multiple-rotation test more closely simulates the action of valve components. The threshold galling stress values for alloys such as type 303, S28200, S42010, S24100, S45500, and type 440C were low (<14 MPa, or 2 ksi), and were greatly reduced, compared with the single-rotation values. For high-silicon alloys, such as S20161 and S21800, improved galling resistance is clearly demonstrated using the triple-rotation test.

(a) Per ASTM G 98.

(b) Did not gall.

(c) Galled at this stress level.

Dissimilar-mated test results (Tables 11 and 13) show the need to screen dissimilar-mated couples prior to service. Some dissimilar couples have threshold galling stress (TGS) values that are higher than either alloy when self-mated and vice versa. For example, type 304 mated with S45500 has a TGS of 124 MPa (18 ksi), whereas their self-mated values are 55 and 90 MPa (8 and 13 ksi), respectively. Type 304 mated with type 440C has a TGS of 28 MPa (4 ksi), whereas self-mated values are 55 and 124 MPa (8 and 18 ksi), respectively.

(a) Did not gall.

In both examples, there is a large difference in hardness between the two members of these couples, but the resultant threshold galling stress values are quite different. For one case, the value is greater than the self-mated values, and for the other, it is lower.

Applications

Various applications for stainless steels can be found where parts are subjected to wear conditions and require the corrosion resistance that stainless steels offer. Several applications have already been discussed, such as coal-handling equipment, where the abrasivity of coal combines with the corrosivity of a wet slurry.

In food-processing equipment, lubricants are prohibited because of sanitation requirements, which means that metal-to-metal sliding can result in wear. For example, most food or drug products must be conveyed down a process line. The roller and side plate interface of a continuous chain-link conveyor belt results in sliding contact. Fine sugar, for example, can be entrapped in sliding parts and further enhances wear. In the food/drug processing industry, fasteners also must be used without the benefit of lubricants. Pump and valve applications are also affected by the sanitation required.

In the exploration for oil and gas, the corrosive environments encountered necessitate the use of stainless steel. For example, drill collars used in oil drilling have threaded connections that are often not effectively lubricated and are prone to galling. Valve parts, often under high pressure and loads, can be prone to galling and thus become ineffective. Leaky valves require repair and costly downtime.

The automotive industry uses programmed valves that redirect the hot exhaust gases away from the carburetor/manifold. A stainless steel was chosen as a stem material because of the elevated temperature (815 °C, or 1500 °F) encountered. In this environment, galling resistance is critical for the valve to last a minimum of 80,500 km (50,000 mi).

In structural fastener applications, corrosion failures of pin-and-hanger bridge assemblies have occurred while using carbon steel. Because of the load of the girders on the pin and hanger assembly, galling and metal-to-metal wear are important concerns; to avoid corrosion failures, however, stainless alloys are being evaluated (Ref 33).

Galling occurred on yacht turnbuckles when silicon bronze was used. Currently in use are stainless steels that have both seawater corrosion and galling resistance.

Because of their longer service life, stainless steels, such as type 304, 3Cr12, and type 410, are replacing carbon steel in corrosive wear applications. The stainless alloys that are more galling and wear resistant, such as S20161 and S21800, are being considered as replacements for Stellite 6B, a cobalt-base alloy, in valve and pump applications, because of their lower cost.

In the nuclear industry, alloys containing high levels of cobalt are being scrutinized, because wear and corrosion products can be released into the primary cooling water and be transported to the reactor core, where Co-59 is transmuted to the radioactive isotope Co-60. Noncobalt-containing stainless steels that are galling and wear resistant are being considered for this application. A family of alloys called NOREM has been developed by the Electric Power Research Institute, and are designed to replace cobalt-containing hardfacing alloys (Ref 34). Several parts that can experience wear and galling problems are shown in Fig. 19.

Design Considerations

For applications in which metal-to-metal wear and galling are of concern, these guidelines should be followed:

- Lubricate where possible
- Keep load, temperature, and speed as low as possible
- Parts should be dimensionally tight with sufficient clearance
- Use a surface finish between 0.25 and 1.75 μm (10 and 70 μin.) whenever possible (many stainless parts are electropolished, which can lead to galling and wear)
- Increase contact area, so that there is less stress on parts and less depth of wear
- Carefully select alloys in unlubricated systems, or where insufficient lubrication may be present. Dissimilar-mated couples with high threshold galling stress values can be chosen or high work-hardening rate austenitic stainless alloys can be selected for improved adhesive and cavitation wear resistance and galling resistance
- Use surface treatments, such as nitriding, hard-face coating, shot peening, and carburizing, which are especially effective in combating fatigue wear

For applications in which either abrasive or corrosive wear is of concern:

- Use a high-hardness martensitic stainless steel when abrasive wear is involved
- Design equipment so that abrasive material flows uniformly
- Minimize the damage that is due to corrosion by designing equipment to minimize standing water or slurry
- Consider the use of stainless alloys when abrasive slurries are encountered

Friction and Wear of Bearing Steels

Charles A. Moyer, The Timken Company

Introduction

REGARDING WEAR for rolling bearing steels, it is important to identify the wear mechanisms that are primarily of concern. Using the mechanisms proposed by Vingsbo (Ref 1), metal loss in bearings is considered to come primarily from abrasive wear, adhesive wear, and contact fatigue wear. Within a properly operating rolling-element bearing, there is generally a minimal amount of sliding that takes place on the primary contact surfaces. The main wear mechanism is contact fatigue. Normally, wear is considered to be accompanied by substantial plastic deformation on or just below the surface, and this is typically the case with abrasive or adhesive wear.

For contact fatigue without gross sliding, the plastic flow that occurs is more localized and can be below what is normally considered surface-related wear and fracture. The depths of maximum shear (orthogonal shear, octahedral shear, or von Mises stress parameter) occur below a rolling contact surface with little surface sliding, tangential force, or surface asperity interaction. This maximum shear depth is on order of 1/50 of the bulk cross section of various bearings. Thus, the whole stress field from a Hertzian contact surface to below any localized maximum subsurface stresses can be defined as the active wear layer for rolling contacts. In this article, bearing steel wear will be considered to include contact fatigue, and the total material involved will range from the surface topography to ~0.1 to 1 mm (~0.004 to 0.04 in.) below the surface. Wear distance for bearing steel under high-cycle fatigue is usually measured within a bearing by how far a point

on one of the bearing raceways has traveled. This distance is usually expressed in total revolutions of one of the raceways or as a percentage of the bearing's expected life.

Composition of Bearing Steels

The steel used in rolling bearings for normal requirements such as industrial or automotive applications is an alloy steel with alloy content, in addition to carbon, that runs from ~1.5 to 6%, depending on the bearing ring cross section and hardenability requirements. However, bearing steels are also known to have reduced non-metallic inclusions so that rolling contact fatigue life requirements can be met. Typical standard bearing steel compositions for high-carbon or through-hardened steels are given in Table 1, and standard bearings steel compositions for low-carbon or carburizing bearing steels are given in Table 2 (Ref 2). Both steels are use depending on specific service condition needs. The advantages of each are pointed out by Burrier (Ref 2). High-carbon steels provide the following advantages:

- Ability to carry somewhat higher contact stresses, such as those encountered in point contact loading in ball bearings
- A simpler quench and temper heat treatment, when compared to carburizing
- Potentially greater dimensional stability under temperature extremes because of their characteristically lower content of retained austenite

Carburizing steels, on the other hand, offer the following advantages:

- Greater surface ductility (due to their retained austenite content) to better resist the stress-raising effects of asperities, misalignment, and debris particles
- A higher level of core toughness to resist through-section fracture under severe service conditions
- A compressive residual surface stress condition to resist bending loads imposed on the ribs of roller bearings, and to reduce the rate of fatigue crack propagation through the cross section
- Easier machining of the base material in manufacturing

Table 1 Nominal compositions of high-carbon bearings steel

Surface hardness on the order of 58 to 64 HRC is present for either high-carbon or carbonizing bearing steels; however, there are some differences in the core hardnesses of these two types of materials. The data in Table 3 show that the strength and toughness of the core are greater in the quenched and tempered low-carbon steels than in the unhardened portion of an induction-hardened high-carbon steel bearing part.

Table 3 Core properties of carburized versus induction-hardened components

From a surface fatigue standpoint, it is necessary to maintain sufficient hardness on and below the surface to resist abrasive/adhesive wear and to minimize contact fatigue in the whole region of the surface and below so that the material strength at each point is higher than the surface or subsurface shear stresses that occur from a loaded Hertzian surface stress. Vingsbo (Ref 1) points out that significant plastic deformation accompanies all forms of wear mechanisms; for contact fatigue it is evident in structural changes and small cell formation. Thus, strength as required can be considered to related to the yield strength of the metal, and the relationship suggested by Pederson and Rice (Ref 3) indicates how this strength varies with hardness (Fig. 1). Because of this, it is not necessarily the steel type that provides the given strength in an operating bearing but how it is treated. If the required hardness is provided from the surface to below the maximum subsurface stresses, then the fatigue resistance of the bearing steel will in general be sufficient.

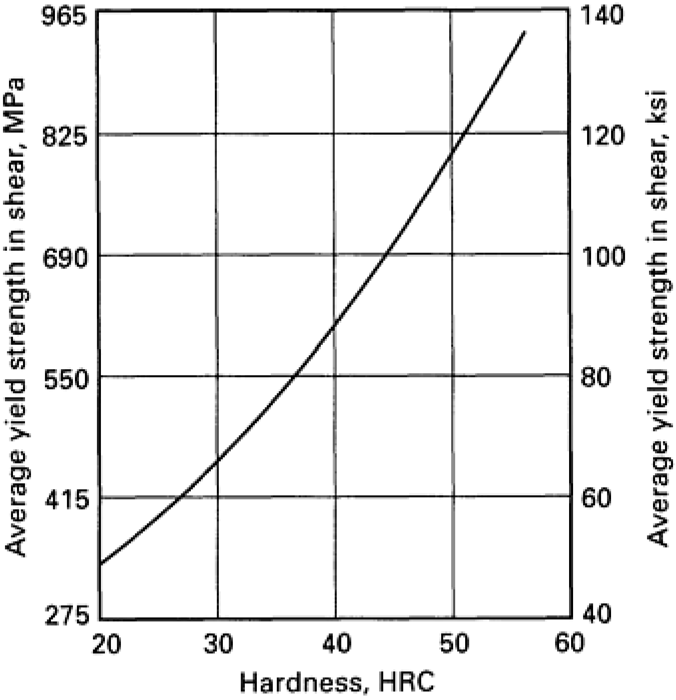

Fig. 1 Plot of shear yield strength versus hardness for typical bearing steel. Source: Ref 3

With proper heat treatment and temper, bearings made from the steels in Tables 1 and 2 should be able to operate in the temperature range of -50 °C (-60 °F) to ~120 to 150 °C (~250 to 300 °F). They should have minimum surface plastic deformation up to Hertzian contact stresses of 2 to 3 GPa (300 to 450 ksi). The Hertzian stress level has a profound effect on the contact fatigue of bearing steels, depending somewhat on bearing type; these differences will be addressed in the section "Concentrated Contacts" in this article.

Beyond the standard bearing steels of Tables 1 and 2, there have been specialty steels developed for either extended fatigue life or excessive operating conditions of temperature and corrosion. These are shown in Tables 4 and 5. In general, these steels have a much higher alloy content, in addition to their carbon content. The high-temperature steels are essentially from 9.3 to 13.5% alloy. CBS-600 is much lower at 4.2%, which is within the range of standard steels; BG42 is higher at 20.5% alloy. Along with different chemistry, these steels usually have significantly smaller and fewer inclusions. Because the bearings made of these materials are used in advanced aircraft engines or aerospace application with ultrahigh speeds, greatly extended fatigue life is required. Rather than air-melt quality, these steels tend to be, for example, vacuum arc remelted (VAR) or vacuum induction melted/vacuum arc remelted (VIM/VAR) for cleanness (that is, freedom from harmful nonmetallic inclusions). Methods of rating the cleanness of such steels are given in Ref 2. Because of the high speeds and the soak back temperatures from adjacent components, these steels usually require the higher temperature capability of about 315 to 370 °C (600 to 700 °F), as indicated in Table 4.

Table 4 Nominal compositions of high-temperature bearing steels

Table 5 Nominal compositions of corrosion-resistant bearing steels

Grade	Composition, %						
	C	**Mn**	**Si**	**Cr**	**Mo**	**V**	**Nb**
BG42	1.15	0.50	0.30	14.50	4.00	1.2	. . .
440C	1.00	0.40	0.30	17.00	0.50	. . .	. . .
440C modified	1.05	0.40	0.30	14.00	4.00	. . .	. . .
CRB-7	1.10	0.35	0.30	14.00	2.0	1.0	0.25

As noted in Table 5, all corrosion-resistant steels have high amounts of chromium. Their alloy content, excluding the high-carbon content, ranges from 17.9 to 20.5%. As might be expected, all these specialty steels with a significant increase in alloy content are more expensive than the standard bearing steels so that the special steels are used only in order to meet the severe requirements of extreme temperature and corrosion. When life requirements are extended, very often six to 10 times the standard duration, then steels with significantly lower levels of nonmetallic inclusions are needed. An example of the extension in fatigue life for cleaner steels is given in Fig. 2 (Ref 4).

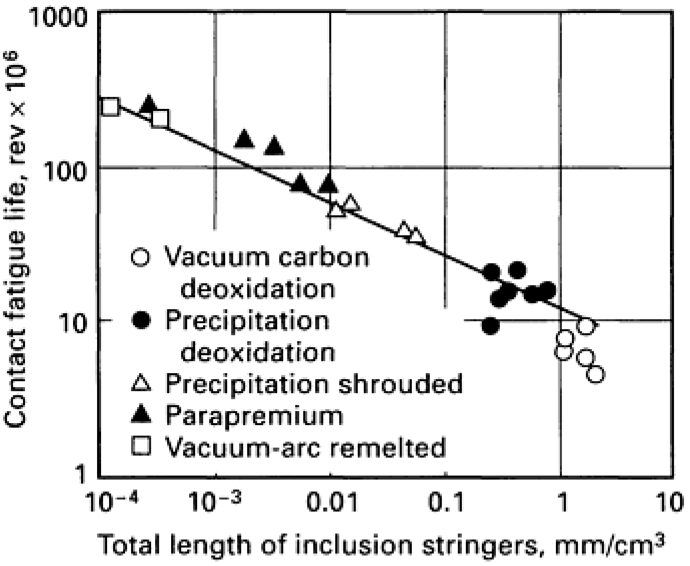

Fig. 2 Effect of total length of inclusion stringers on the rolling contact fatigue life of a 220 mm (8.7 in.) bore tapered roller bearing inner race as a function of steel cleanliness. Source: Ref 4

Cleanness level can be measured by the size and distribution of inclusion stringers that are left from the processing of steel. The presence of inclusions in a bearing component can be quantified by means of enhanced ultrasonic detection methods (Ref 4). Quantified ultrasonic results are supplemented with inclusion imaging and length verification using acoustic microscopy (see the article "Acoustic Microscopy" in this Volume). These tools, along with energy-dispersive or wavelength-dispersive chemical analyses using scanning electron microscopy (SEM), have confirmed that aluminum oxide stringers relate directly with bearing fatigue life under operating conditions that promote material fatigue. The size distribution and the total quantity of inclusion stringers in a given group of bearings has been shown to relate to performance (fatigue life) through a summation of the inclusion stringer lengths per unit volume of steel.

The total length in inclusion stringers per unit volume is the abscissa on Fig. 2. The steel cleanness range starts with an earlier vacuum carbon deoxidation steel process method of about 10 years ago to the precipitation-shrouded version of

today's air-melt steels and to today's vacuum-arc remelted steel. As shown in Fig. 2, the overall fatigue life range is more than an order of magnitude. VIM/VAR steel lives exceed even the VAR steel lives so that even though the present-day air-melt steels do give better lives, the vacuum-processed steels are meeting the fatigue life requirements for the extended-life applications.

Bearing steels are sometimes used for gears, cams, and other concentrated-contact applications. However, whenever the requirements of much higher surface sliding (tangential forces) are present in these other contacts, other slightly different chemistries may be specified and certainly differing steel treatments and processing will be required to better meet the contact conditions of sliding, rougher surfaces, and even the presence of bending fatigue. In general, bearing steels are limited to rolling contact bearings based on surface hardness requirements, harden-ability, and cleanness level in order to minimize nonmetallic inclusion fatigue.

Concentrated Contacts

In an operating rolling contact bearing, the instantaneous action takes place within the concentrated contacts formed between the bearing raceway and roller or ball surfaces. Figure 3 is a simplified diagram of such a contact showing two surfaces with curvature brought together by load to form a Hertzian stress field with maximum contact pressure, *P*, as shown. The longer length of contact is usually transverse to the direction of motion, and the narrower width of contact, 2*b*, for smaller to medium size bearings, will be on the order of 0.1 to 1 mm (0.004 to 0.04 in.). The contact tends to be a rectangle for line contact and an ellipse for point contact (usually ball bearings). However, if there is a curvature or profile on one or both surfaces in the transverse direction, even roller bearings can have essentially elliptical or truncated elliptical contact, depending on the load level.

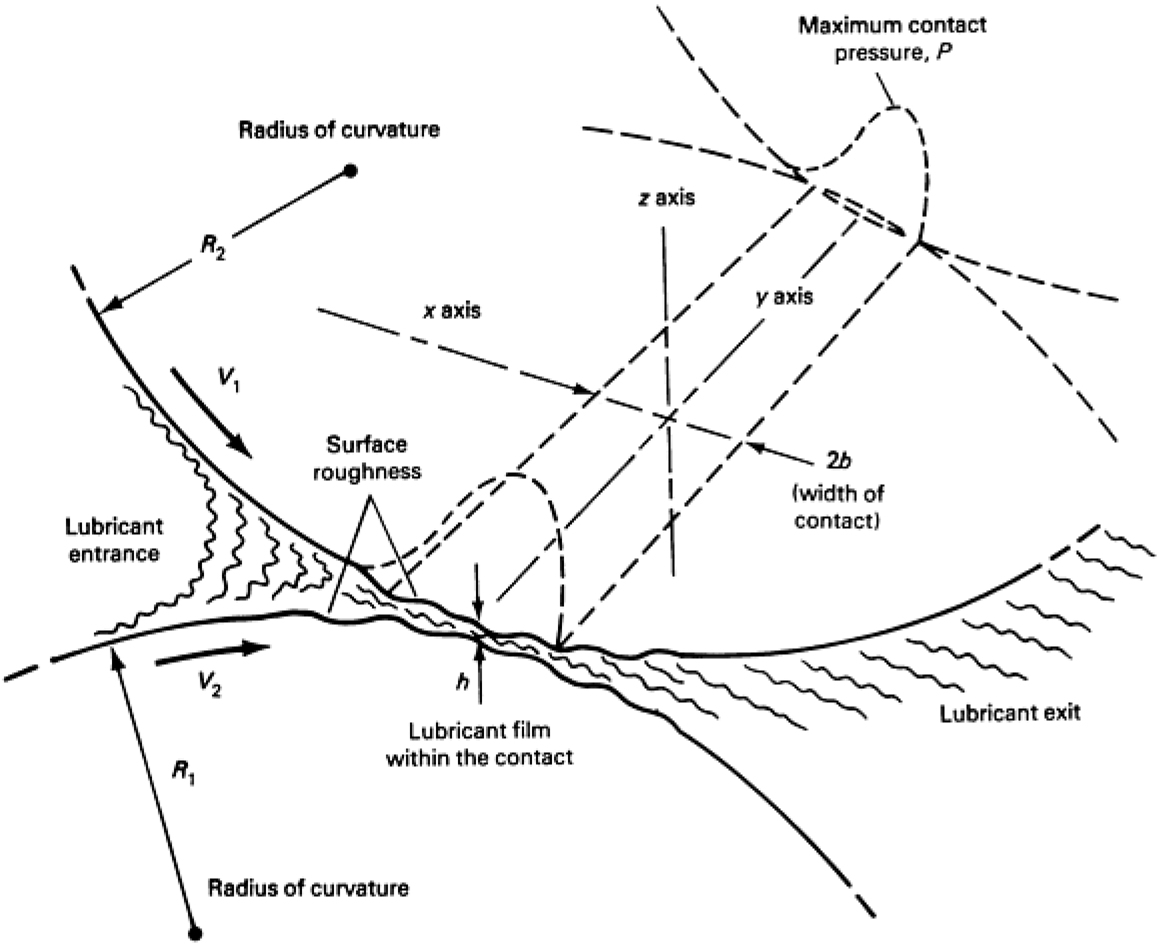

Fig. 3 Schematic showing key components of tribological contact between a raceway and the rolling elements of a steel bearing

The moving surfaces entrain lubricant into the contact and form a lubricant film with thickness, *h,* that partially or completely separates the surfaces from contacting. The film thickness can be calculated using elastohydrodynamic theory (Ref 5, 6, 7) that recognizes the exponential increase in the lubricant viscosity within the Hertzian field and the local elastic deformation of the bearing steel surfaces that form the contact area. (Details of how to determine the thickness of a lubricant film are given in Ref 5, 6, 7.) The contacting steel surfaces in a bearing are finished by grinding, which is usually followed by some superfinishing process (for example, honing). Larger bearings may only have a ground surface. Whatever the finishing method, there is some roughness left on the bearing steel surfaces, as indicated in Fig. 3. The peaks or asperities of the surface may penetrate the lubricant film, depending on the surface roughness and the thickness of the film controlled by the operating viscosity; the pressure viscosity at operating temperature; the surface velocities, V_1 and V_2; the radii of curvature; and to a lesser extent, the prevailing load.

The lubricant film thickness divided by the combined roughness of the two surfaces has been called the specific film thickness or the lambda ratio, Λ. Specific film thickness has been a popular method for describing the operating conditions within the contact for over 20 years (Ref 8). Numerous wear and fatigue tests have been reported comparing the result for $0.1 \leq \Lambda < 20$. Figure 4 is an example of eight test groups of a specific size ball bearing (45 × 100 mm, or 1.8 × 3.9 in., deep-groove ball bearing of through-hardened 52100 steel) (Ref 9), and Fig. 5 shows 11 test groups of a specific roller bearing size (46 × 85 mm, or 1.8 × 3.3 in., tapered roller bearing of carburized and hardened 8620 steel) (Ref 10). For these specific bearings, the fit of the test groups was by confidence bands (0.95) for the ball bearings and a regression coefficient (0.88) for the tapered roller bearings, indicating that for each of these bearings a reasonable predicting equation was developed:

- For the ball bearing data:

$$L_{10} = C \cdot \Lambda^{0.54} \qquad \textbf{(Eq 1)}$$

- where L_{10} is the bearing life for 90% reliability, Λ is the lambda ratio ranging from ~0.7 to 20, and C is the constant developed from the specific tests
- For the tapered roller bearing data:

$$L_R = C \cdot \Lambda^{0.86} \qquad \textbf{(Eq 2)}$$

- where L_R is the bearing life in terms of ratio to catalog expected life (that is, relative fatigue life), Λ is the lambda ratio ranging from 0.04 to 0.3, and C is the constant developed from the specific tests

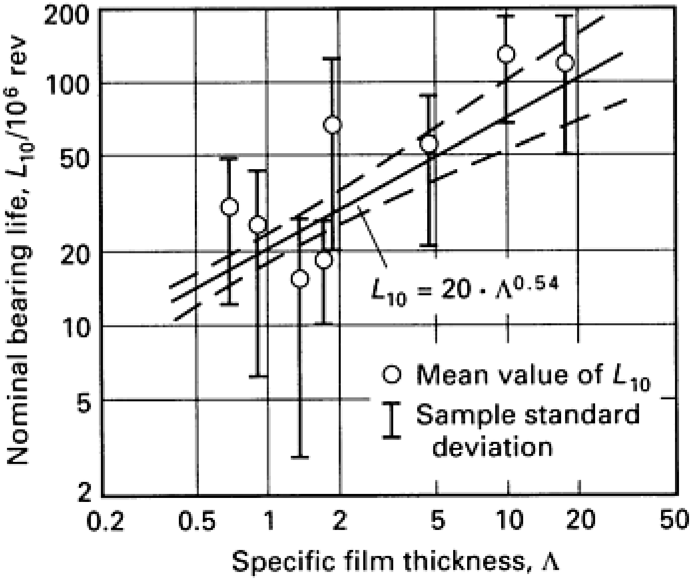

Fig. 4 Plot of normal bearing life versus specific film thickness for 45 × 100 mm ($1\frac{3}{4}$ × 3.9 in.) deep-groove ball bearings made of through-hardened 52100 bearing steel. Data were compiled for eight test groups totaling 6309 bearing units. Confidence limits are 95%. Source: Ref 9

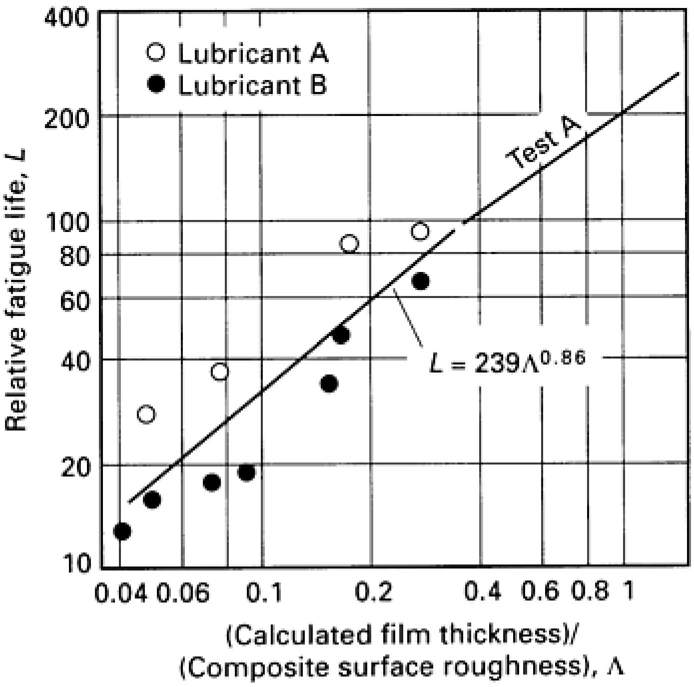

Fig. 5 Plot of relative fatigue life versus specific film thickness, Λ, for 46 × 85 mm (1.8 × 3.3 in.) tapered roller bearings made of carburized and hardened 8620 steel. Data were compiled for 11 test groups with 88% correlation coefficient on the regression line. Test A represents results from previous testing. Source: Ref 10

Because Λ represents the operating condition within a bearing steel contact and because the simple lambda ratio seems to relate well to fatigue life (as Fig. 4 and 5 indicate), there have been attempts to combine much published data and develop a general relationship between Λ and fatigue wear. Figure 6 shows a significant attempt to combine the results from seven different sources of both ball bearing and roller bearing tests (Ref 11). Note that Λ does relate to the relative life factor, $N(\Lambda)/N_{cat}$, but there is considerable scatter due to other factors that cause variation in fatigue life. There is no question, however, that bearing steel contact fatigue wear is significantly affected by the contact lubricant operating conditions.

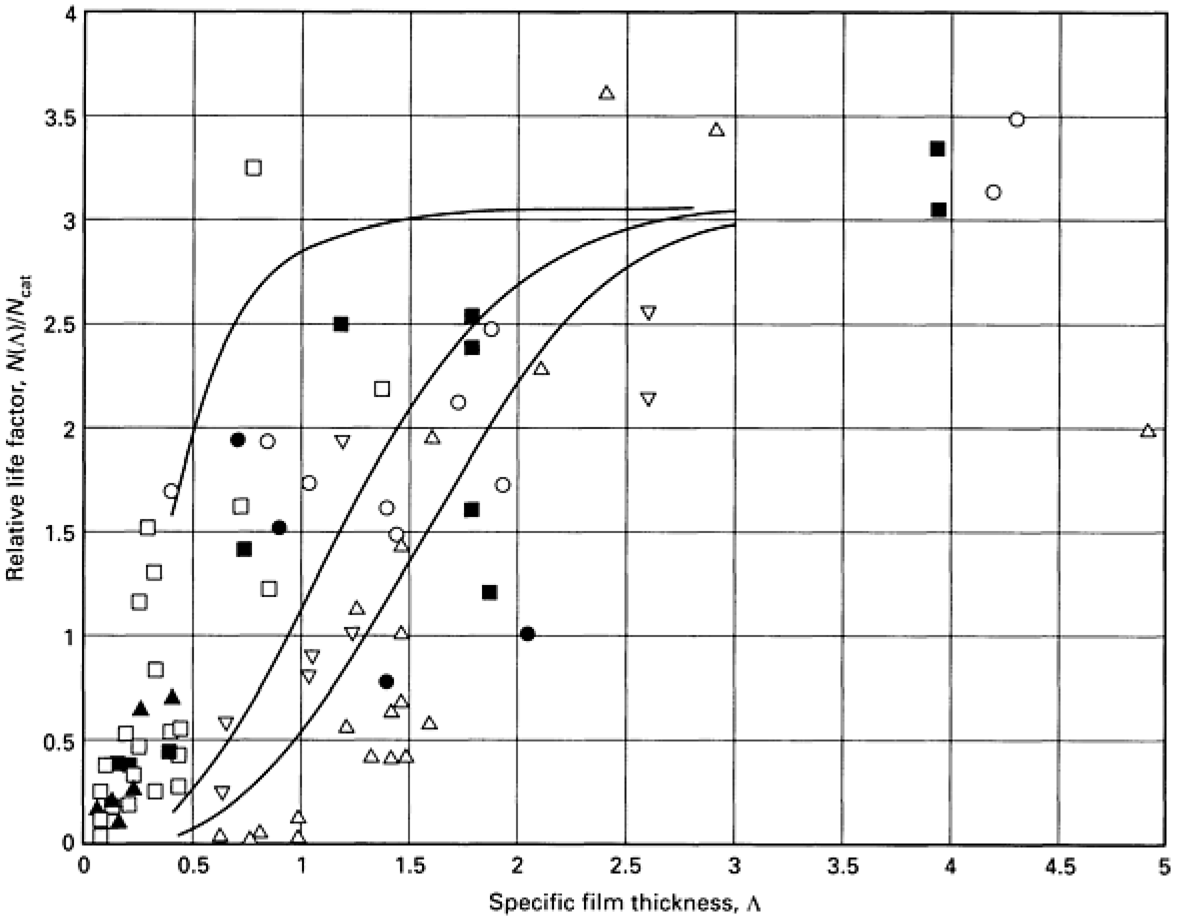

Fig. 6 Plot of relative lives versus specific film thickness as a function of selected asperity slope curves: A, 48', the smoothest surface; B, 2°, the median surface; C, 3°30', the roughest surface. Data points shown represent work of seven researchers. Source: Ref 11

Roughness or surface topography is not an intrinsic property of the material or surface (Ref 12) but depends on how it was processed and finished and on how the range of wavelengths of the topography interact with the bearing steel contact, especially the width 2*b* in the rolling direction (Ref 13). Tallian (Ref 11) has proposed the use of asperity slope to more completely describe roughness as it influences Λ(Fig. 6). The inference is that bearing steel surfaces having sharper asperities may have lower life than surfaces having broader asperities. Although these curves did not agree with some of the actual groups of test bearings, the premise is sound. This scatter also indicates that Λmay need to be modified to better represent roughness for the range of bearing sizes and contacts that are represented in Fig. 6 (Ref 8).

Lambda Ratio and Modes of Wear

Another important factor relating to Λconcerns the change in mode of contact fatigue for different values of Λ. This also relates to the presence of the other bearing steel wear mechanisms that depend on the value of Λ. Table 6 is a simplified listing of the modes of wear or damage classification for bearings. When $\Lambda$is > 3, almost complete separation of the surfaces occurs and minimal adhesive or abrasive wear takes place. Bearing steel contact fatigue wear is essentially all subsurface at the regions of maximum shear so that all fatigue is material related and primarily inclusion initiated. This subsurface region is roughly 0.25 to 0.5 times the width of contact (2*b*) below the surface. Under these conditions, the steel is expected to meet or exceed the rating life for the bearings. The experimentally determined load-life equation below is valid for current bearings of steel described in Tables 1 and 2:

$$L_{10} = \left(\frac{C}{P}\right)^n \cdot 10^6 \text{ rev} \qquad \textbf{(Eq 3)}$$

where L_{10} is the rating life with 90% reliability (in revolutions), C is the basic dynamic capacity, C_R (radial) or C_T (thrust), based on the rating equations given in Ref 14 and 15, P is the equivalent radial load or equivalent thrust load to match C_R or C_T, and n is the load exponent (experimentally based with consensus values published in the bearing standards) (Ref 14 and 15); typically, n = 3 for ball bearings and n = 10/3 for roller bearings.

Table 6 Wear mode or damage classification for bearing steels

Contract fatigue	
Subsurface origin: Inclusion	Within macroshear classical shear stress zone below contact surface
	Near surface zone of microshear greatly affected by surface roughness (asperites)
Subsurface origin: Subcase fatigue	Origin near case-core interface if yeld strength is exceeded by applied stress
Surface origin	Origin at the end of contact aggravated by edge geometry
	Multiple origins of micropitting (peeling or frosting)
	Point surface origin at localized stress risers (dents, grooves, surface inclusions)
Plastic flow	
Brinelling or debris denting	
Load excursions above the material yield point	
Yielding aggravated by high-temperature excusions	
Wear	
Adhesive	Normal: Mild or "controlled" (usually identified as "run-in")
	Severe: Irreversible scuffing, scoring, smearing, or seizure
Abrasive	Normal: Ususally three-body system, mediaum to fine particles that are also associated with "run-in"
	Severe: Grooving, gouging, denting with ridges that cause serious surface stress risers
Corrosive	Water or acidic constitutents from lubricant breakdown or temperature, chemically aggressive additives in lubricant
Fretting	Microscale adhesive and abrasice wear
	Corrosion involvement depending on environment and contacts

Considering the exponents on the load ratio, it is clear that load is the most significant factor in bearing life (contact fatigue). From Eq 3, for loads of 0.1 to 0.4 C, the life ratios in Table 7 hold.

Table 7 Effect of load on bearing life

Life ratio, C/P	Ball bearings $(C/P)^3$	Roller bearings $(C/P)^{10/3}$
10.0	1000	2150
2.5	16	21

Thus, for ball bearings, reducing the load by one-fourth will results in >60 times bearing life and for roller bearings, one-fourth less load results in >100 times bearing life. The data in Table 7 assume only inclusion, bearing steel related fatigue, and contact fatigue wear as represented by Eq 3.

With $\Lambda < 3$, more asperity interaction will take place in the contact (per Fig. 3 and Table 6; inclusions in the near-surface zone may also be involved). With $\Lambda < 1.0$, there can be significant changes to the surface traction so that the level and region of subsurface and near-surface shear stress increases, leading to reduction in fatigue life. The change in one particular stress, orthogonal shear reversal range, is indicated on Fig. 7. As the coefficient of friction, μ, reflecting the increased tangential surface force goes up, the surface shear stress could eventually match that of the subsurface so that a much larger volume of material below the bearing steel surface is subjected to higher shear stresses. For example, under normal operating conditions, the coefficient of friction between the raceway and roller for tapered roller bearings has been measured from 0.001 to 0.005 (Ref 17). The bearings were 76 mm (3.0 in.) bore by 162 mm (6.38 in.) outside diameter in size. The increase in the coefficient of friction followed speed changes from 1500 to 500 rev/min, the lambda ratio, Λ, decreasing from 2.5 to 0.5. These measured values are low and probably include other friction losses besides the surface traction. However, the decrease in the value of Λ was clearly accompanied by greater surface traction and increased asperity interaction. An indication of how such a change in traction with Λ held constant might reduce bearing life is shown in Fig. 8. The data points are from Ref 18 and show measured traction coefficients for tests with slide/roll ratios that varied from 0 to 0.8%. The three points show actual relative fatigue lives $N/N_{\mu e=0}$ for rolling balls tested at 6 GPa

(870 ksi). The approximate Λ over the slide/roll ratio range was estimated at 1.25 (Ref 11). Therefore, surface friction forces can be changed by the amount of sliding, by Λ changes, or usually by the combination of both.

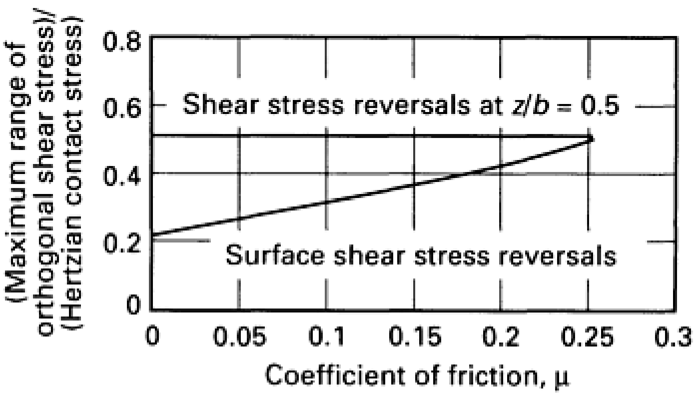

Fig. 7 Plot of the coefficient of friction versus the ratio of the maximum range of orthogonal shear stress to the Hertzian contact stress. (*z*/*b*) = 0.5 is the distance below the surface in the *z* direction (Fig. 3) relative to contact width 2*b*. Source: Ref 16

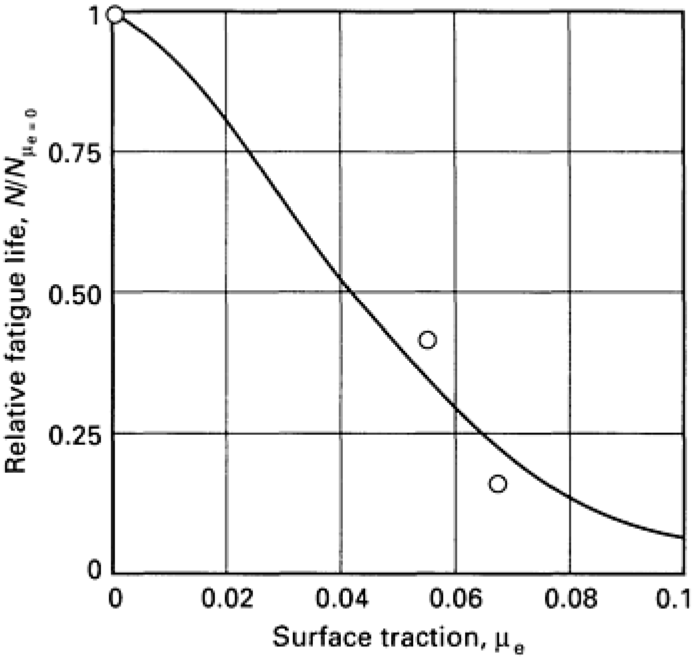

Fig. 8 Plot of relative fatigue life, $N/N_{\mu e=0}$, versus surface traction. $N_{\mu e=0}$ is fatigue life when traction equals zero. Model parameters: asperity slope, 2°; specific film thickness, Λ, 1.25. Source: Ref 11, 18

For $\Lambda < 1.0$, because of the increased asperity contact, and if significant increases in traction can occur, subsurface fatigue gives way to near-surface fatigue (high stress pockets below the highest, sharpest asperities). With Λ even lower, failure can change to surface fatigue, often initiated by surface defects. Dents, deep grinding grooves, handling nicks, surface inclusions, and so on, are now the prime stress raisers rather than nonmetallic inclusions within the steel. The failure modes resulting from the surface defects are described in Table 6. One mode is point surface origin fatigue in which the fatigue propagation fans out from the point in an arrowhead fashion. Other surface-related fatigue can come from misalignment in a ball or roller bearing that reaches the end of the raceway (geometric stress point); or because of the topography (roughness of the asperities), fatigue can develop as multiple pitting, which appears as frosting or peeling.

Under these conditions, fatigue life drops as indicated in Fig. 5 and 6. Equation 3 is no longer valid and L_{10} must be adjusted because rating life will no longer be attained. The bearing industry recognized the need to be able to adjust L_{10} when the concept of life adjustment factors was introduced in 1972 (Ref 19). Equation 4 indicates the general approach to life adjustment:

$$L_{na} = a_1 \cdot a_2 \cdot a_3 \cdot \left(\frac{C}{P}\right)^n \cdot 10^6 \text{ rev} \quad \textbf{(Eq 4)}$$

Or by adjusting rating life, L_{10}:

$$L_{na} = a_1 \cdot a_2 \cdot a_3 \cdot L_{10} \quad \textbf{(Eq 5)}$$

where L_{na} is the calculated life (in rev) adjusted by the multiplicative factors, a_1, a_2, and a_3; a_1 is the reliability factor for other than 90% reliability; a_2 is the material factor for other than standard bearing steels; and a_3 is the application or environmental factor, primarily recognizing the lubricant condition within a bearing; a_3 also can include alignment, internal load distribution changes, temperature, contaminants (liquid and solid), and fatigue spall criteria.

Reliability Factor a_1. The reliability factor is based on the life scatter experienced by a group of apparently identical bearings running under the same load, same Λ or same environmental conditions. This scatter is quantified by the Weibull distribution, specifically the Weibull slope (m) or dispersion parameter. The general equation for this is:

$$a_1 = [9.4912 \ln(100/R)]^{1/m} \quad \textbf{(Eq 6)}$$

where a_1 is the reliability factor to adjust the L_{10} life, R is the reliability expressed in terms of percent survival, and m is the Weibull slope, for reliability >90%. The value of m is 1.5 in the bearing standards. Background data for establishing the Weibull slopes for ball bearings and roller bearings are in Ref 20 and 21, respectively.

Material Factor a_2. Recognizing that cleaner steel (that is, steel with fewer and smaller inclusions) is being used in today's bearings, most bearing manufacturers have increased ratings in the last several years so that the fatigue constants present in various rating equations reflect the increased fatigue life expected from the present steels. The 1990 rating standards reflect this in a generic way within the present bearing ratings given in Ref 14 and 15. Because of the considerable experimental basis required to establish specific bearing ratings (that is, the fatigue constant, the Weibull slope, and the load-life exponent, along with specific material heat treatment and processing differences), the determination of contact fatigue wear of bearing steel alone is difficult to extract from the rating equations. Thus, a_2 is not the kind of factor that can be used as a typical wear rate coefficient. The material factor a_2 was initially developed to recognize the ultraclean steels (that is, VAR, VIM/VAR, or electroslag remelting, or ESR) that could give significantly longer lives or increased reliability in special bearing applications that could justify the increased cost of such steels. This is still the primary use of a_2 in the aerospace industry and other industries requiring extended-life bearings.

Application of Environmental Condition Factor a_3. A simple summary of the subfactors that make up the factor a_3 is given in Table 8. The subfactors listed relate directly with the bearing contacts. As would be expected, the lubricant--usually the elastohydrodynamic lubricant (EHL) film compared to the surface roughness, very often as Λ--is an important subfactor. However, the lubricant can be a mineral oil, synthetic, or other fluid, with properties of viscosity, pressure viscosity, surface wetting ability, surface tension, and shear strain-stress relationships that are enhanced or degraded depending on the additive mix, their particular formulation, and how any of these change over time. Unfortunately, there is only limited information about how changes in these properties impact Λ or relate to bearing steel fatigue or wear.

Table 8 Operating conditions impacting bearing performance that are subfactors of application or environmental factor, a_3

Lubricant--surface topography	**These control how surfaces interact (EHL film/composite roughness as lambda ratio is the primary model used)**
Temperature--speed	Bulk conditions such as these control the concentrated contacts of a bearing
Load zone--alignment	Factors impacting load and actual stress within all the active contacts in a bearing
Fatigue spall criteria	Definitions of initiation and propagation as these impact the actual lives of bearings in an application
Contaminants	Liquid and solid that can flow through a contact

Bearings operating at a given speed (and load) tend to reach an operating bulk temperature for the bearing steel that establishes the temperature for the lubricant coming into the contact. Although this temperature may be difficult to determine, any attempts at calculating the lubricant film within the bearing require as accurate an assessment of this operating temperature as possible. The heat generated within a bearing can be better understood by the following equation:

$$Q_{gen} = \text{function}(S)^{3/2}, (\mu)^{1/2}, (F)^{1/3} \quad \textbf{(Eq 7)}$$

where Q_{gen} is the heat generation (in watts), S is the rotational speed, μ is the lubricant viscosity at bearing operating temperature (in centipoise), and F is the load (in Newtons).

The point of this simple function is to recognize how bearing steel temperature will change depending on changes to speed, viscosity, and load and that the contribution of these factors to temperature change is not the same. Therefore, changes in any of the factors given in Eq 7 will affect operating temperature, the lubricant film, and the operating conditions represented by Λ.

Depending on the external loading on a bearing, radial or thrust, with overturning moments, along with any internal clearance (or lack thereof), there can be sizeable internal load variation, shifting the amount of loading on each rolling element. Depending on the magnitude of the overturning moments or deflections, excessive misalignment can occur. Table 9 gives approximate allowable misalignment for bearings before reduction in life can occur. This misalignment results in nonuniform stress being applied to the steel, and fatigue or wear occurs at the region of the highest stresses.

Table 9 Allowable misalignment in rolling-element bearings before bearing life is affected

Bearing type	Misalignment		
	Radians	**in./in.**	**Degrees**
Cylindrical and tapered bearings	0.0005-0.001	0.0005-0.001	0.03-0.06
Ball bearings	0.003-0.005	0.003-0.005	0.17-0.29

Fatigue spall criteria are normally defined as the first evidence of fatigue or by the size of the spall, such as 3 mm ($\frac{1}{8}$ in.) diameter (Ref 9) or 6 mm^2 (0.01 in.^{2}) (Ref 10). Whether a bearing has any useful life beyond this beginning spall size depends on the operating conditions that control the rate of fatigue spall propagation. For mild operating conditions with lower temperature, reasonable speeds, and lubricant film that provide $\Lambda > 1.0$, it may be possible to run until 10% or some portion of a raceway is spalled. However, under thin-film conditions, especially at higher temperatures and heavy loads ($C/P < 4.0$), fatigue propagation may be so rapid that no extension of bearing life beyond the first detection of a fatigue spall can be expected.

Contaminants within a steel bearing can cause considerable damage and lower fatigue life. Rough running, excessive friction, overheating, and other forms of wear can occur from contaminants; therefore, proper filtration and sealing are important. The extent of filtration required depends on the bearing size and type selected. Acid formation from lubricant breakdown and the presence of water can be especially damaging. The steel can experience surface etching and corrosive wear. An indication of the impact of water alone is shown in Fig. 9.

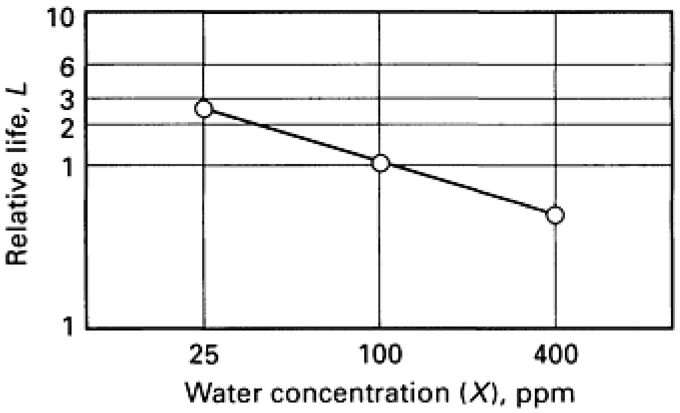

Fig. 9 Plot of relative bearing life, *L*, versus water concentration, *X*, where $L = (100/X)^{0.6}$. At 100 ppm concentration, $L = 1$. Source: Ref 22

Solid contaminants or debris are also damaging in their ability to collect in the inlet region of a bearing contact, thereby causing lubricant starvation (Ref 23). Debris may also cause dents on the bearing steel surface that are large enough to be stress raisers, lowering contact life significantly. Debris that passes continuously through a bearing contact tends to be shattered or deformed into much smaller pieces. These form an exponential-type distribution within a closed or circulating lubricant system. The debris particle sizes can range from >100 μm (>0.004 in.) (usually only a few particles approach this size) to a middle range of ~50 to 5 μm (~2000 to 200 μin.) (from hundreds to thousands of particles) to particles <5 μm (<200 μin.) (depending on the source, quantities can be into the millions). The largest particles cause the dents that affect fatigue life. The middle range can contribute to abrasive wear in bearings (and fatigue loss from denting in bearings with smaller contacts, especially small ball bearings). Finally, the smallest size particles cause mild wear in larger bearings and serious abrasive wear in small bearings with contact lengths <5 mm (<0.2 in.).

The ability to determine the loss of fatigue life from debris denting is in the developing stage. A subfactor of a_3 that can account for the size and side slope of the dent relative to the contact size and the tolerance of the material (both in terms of hardness and fracture toughness) will be required (Ref 24, 25, 26). Carburized bearing steels with considerably higher fracture toughness (Fig. 10) tend to be more tolerant than through-hardened steels to the consequences of debris denting. This tolerance is also dependent on the amount of retained austenite present in the surface layer.

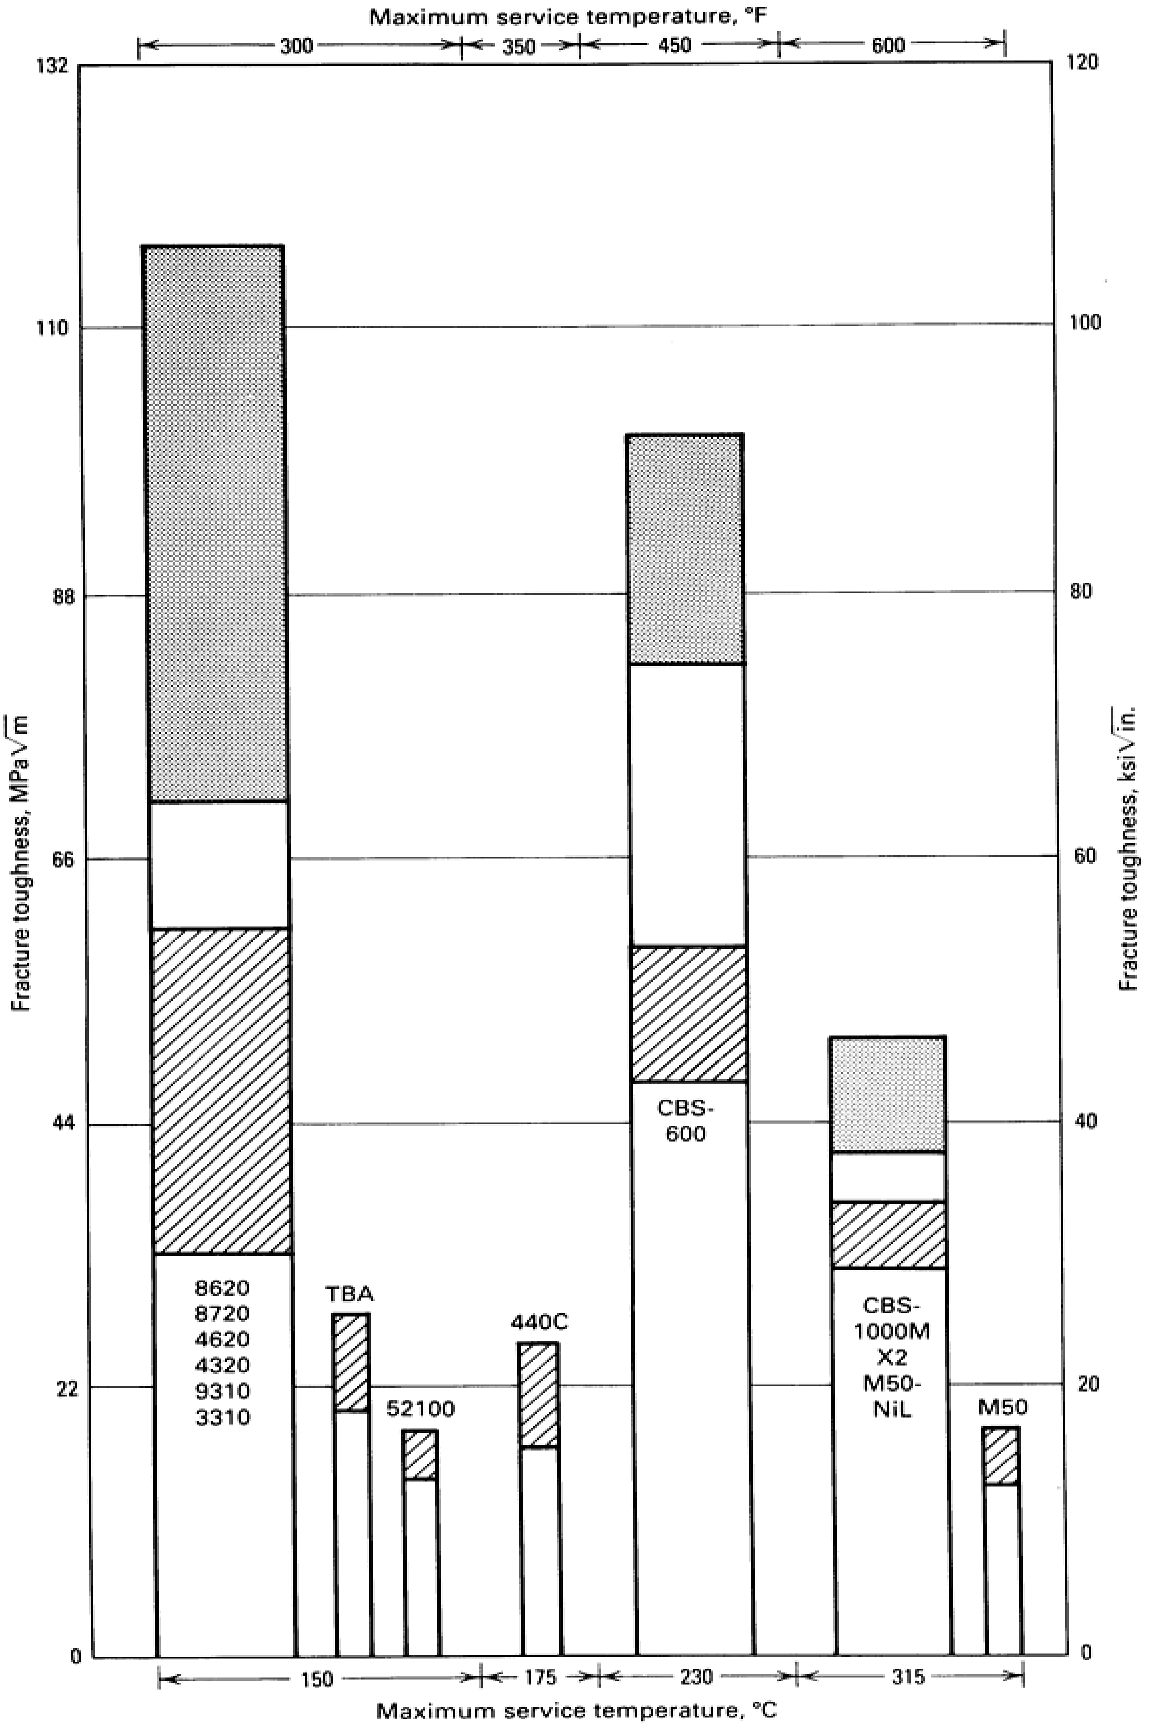

Fig. 10 Composite fracture toughness of carburizing and homogeneous high-carbon steels in slow bending. Case depth is 0.76 to 0.89 mm (0.030 to 0.035 in.) to 0.50% C level. Shaded areas indicate range of *K* values for cracks originating in core. Cross-hatched areas indicate range of *K* values for cracks originating in case. Charpy-sized specimens were carburized, hardened, tempered, and precracked to several depths in case and

core regions before testing. As cracks progress inward, the fracture resistance of carburized composites improves significantly.

Abrasive Wear

In most applications, rolling bearings do not experience appreciable abrasive or adhesive wear. There are some wear particles formed from the run-in that bearings undergo in the initial period of operation. If there is some denting on the bearing, wear can also take place. A 45 × 100 mm (1.8 × 4 in.) ball bearing and a 45.2 × 73 mm (1.78 × 2.9 in.) tapered roller bearing were each dented by a Vickers hardness indenter at two places on the inner raceway. The ball and tapered roller bearings were then each run in a clean, closed lubricant system (Ref 27), and they developed wear particles that in total weighed about 15 and 25 mg (0.23 and 0.39 gr), respectively (Ref 24). It was estimated that the ball bearing generated 2×10^5 particles, in a size range of 10 to 30 μm (400 to 1200 μin.), running with a Λ value of 1.8; the tapered roller bearing generated about 8×10^4 particles in a size range about 5 to 50 μm (200 to 2000 μin.), running with a Λ value of ~1.1 (Ref 27). Therefore, with reasonable lambda ratio and no debris added, bearings should experience only mild wear during run-in or with some denting. If debris of sufficient size and quantity enters a lubricant system, then a bearing will have considerable wear.

A series of bearing wear tests have been conducted in a two-chamber bearing wear machine of the type shown in Fig. 11 (Ref 28). Each chamber has a small 33.3 × 68.3 mm (1.31 × 2.69 in.) tapered roller bearing with 250 cm^3 (8.5 oz) of an SAE 80 EP gear oil (1.3×10^{-5} m^2/s, or 13 cSt) in the closed system. The lubricant contains a measured amount of debris, usually silica dust, of known size range. The debris is kept in suspension by the flingers attached to the integral rotating shaft. The test runs at 2700 rev/min with $\Lambda \sim 0.8$, a thrust load giving 1 GPa (150 ksi) stress, and for 40 h (6.5×10^6 rev duration). Four bearings tested with silica dust in a sequence of 2, 5, 10, and 40 h, which cleaning and weighing at each stop, show the high rate of initial wear and the gradual leveling off by 40 h (Fig. 12). There has not been a change in the bearing steel, but the debris particles are so crushed that most pass through the contact film and can no longer cause wear.

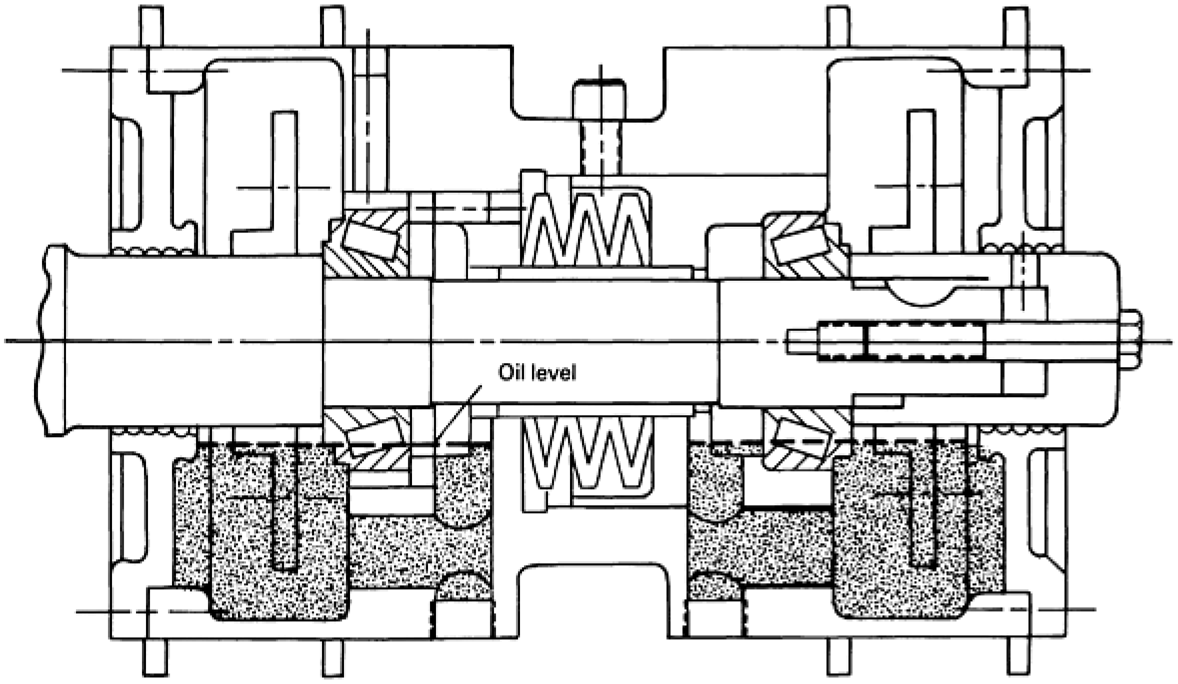

Fig. 11 Schematic showing cross-sectional view of a two-chamber bearing wear machine

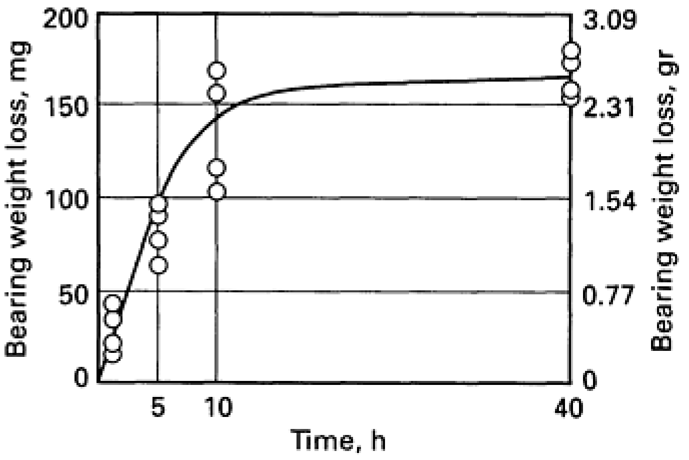

Fig. 12 Plot of bearing wear versus time for 33.3 × 68.3 mm (1.31 × 2.69 in.) tapered roller bearings using data obtained with the bearing wear machine shown in Fig. 11. Test conditions: lubricant, SAE 80 EP gear oil with 1.3 × 10^{-5} m^2/s (13 cSt) viscosity used at temperatures of 90 to 100 °C (190 to 210 °F); contaminant, uncut silica dust with concentration of 1000 mg/L (60 gr/gal)

Repeat tests demonstrated that reasonable wear data could be generated with this tester. Tests with no debris and with debris concentrations of 250, 500, 750, and 1000 mg/L (15, 30, 45, and 60 gr/gal) indicated that a linear relationship between debris (particle) concentration and wear (milligrams of weight loss) exists with a regression correlation coefficient of 0.95. Additional tests of the same debris concentration range, but with different cuts of silica dust (particle size ranges) indicated the same linear relationship but no significant difference between the debris size ranges (Fig. 13).

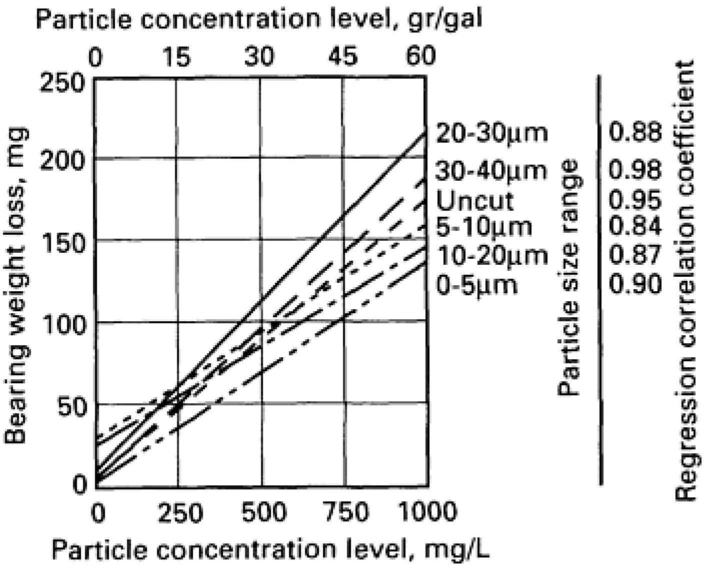

Fig. 13 Plot of bearing weight loss versus particle concentration level as a function of particle size range. Test parameters: lubricant, SAE 80 EP gear oil used at temperature of 90 to 100 °C (190 to 210 °F); contaminant, silica dust; test duration, 40 h

The maximum weight loss of about 200 mg (3 gr) for this small bearing would cause borderline internal dimensional changes in the bearing. the debris concentration, 1000 mg/L (60 gr/gal), if considered from a volume standpoint, may be a better comparison. The volume of silica to the volume (liter) of lubricant would be about 450 ppm. However, weight losses of two to three times this 200 mg (3 gr) level could cause serious internal geometry damage to the bearing.

Figure 14 indicates the amount of wear that occurs with debris contaminants of different hardness level. The silica fine uncut dust line can be considered the reference line. The bearing steel debris then caused about 60% of the wear from silica, and the carbonyl iron produced no more than 5% of silica wear. The diamond dust caused extreme wear. The bearings were badly damaged and the tests were stopped considerably before the 10 h time limit. Figure 15 shows how different lubricants can affect abrasive wear of bearing steel. The amount of wear increases as viscosity decreases for the mineral oils and the extreme-pressure (EP) gear oil. The differences are shown in Table 10.

Table 10 Effect of selected lubricants on the abrasive wear of bearing steels

Lubricant	Viscosity at 95 °C (200 °F)		Wear[a]	
	SUS[d]	**Kinetic viscosity, cSt**	**mg**	**gr[e]**
SAE 140[b]	180	38.3	60	0.90
SAE 50[c]	110	22.7	75	1.16
SAE 30[c]	71	13.2	95	1.46
SAE 5[c]	41	4.5	125	1.93
SAE 90[b]	85	16.8	145	2.23
SAE 80[b]	65	11.6	170	2.62

(a) Bearing weight loss at 1000 mg/L (60 gr/gal) debris concentration.

(b) EP gear oil.

(c) Mineral oil.

(e) gr, grain

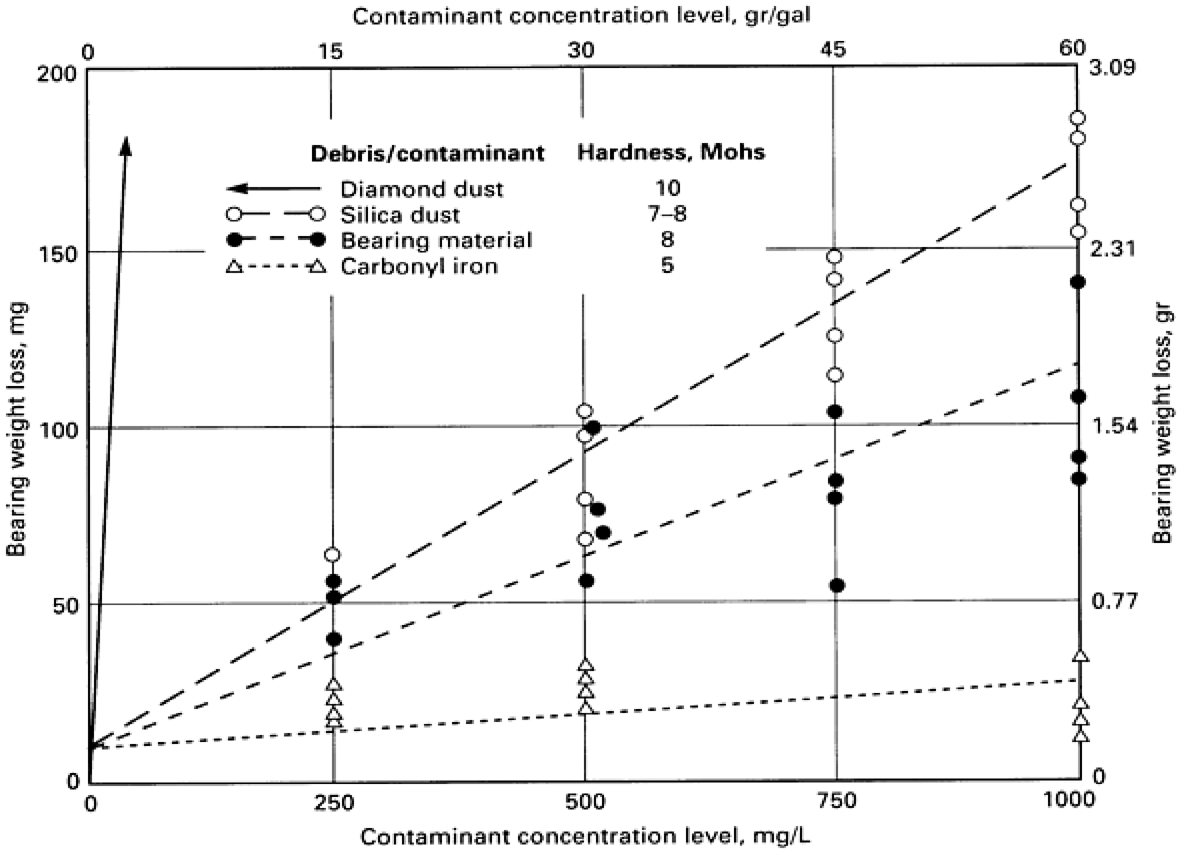

Fig. 14 Plot of bearing weight loss versus contaminant/debris concentration level as a function of four selected contaminants of varying hardness. Test parameters: lubricant, SAE 80 EP gear oil used at temperature of 90 to 100 °C (190 to 210 °F); test duration, 10 h

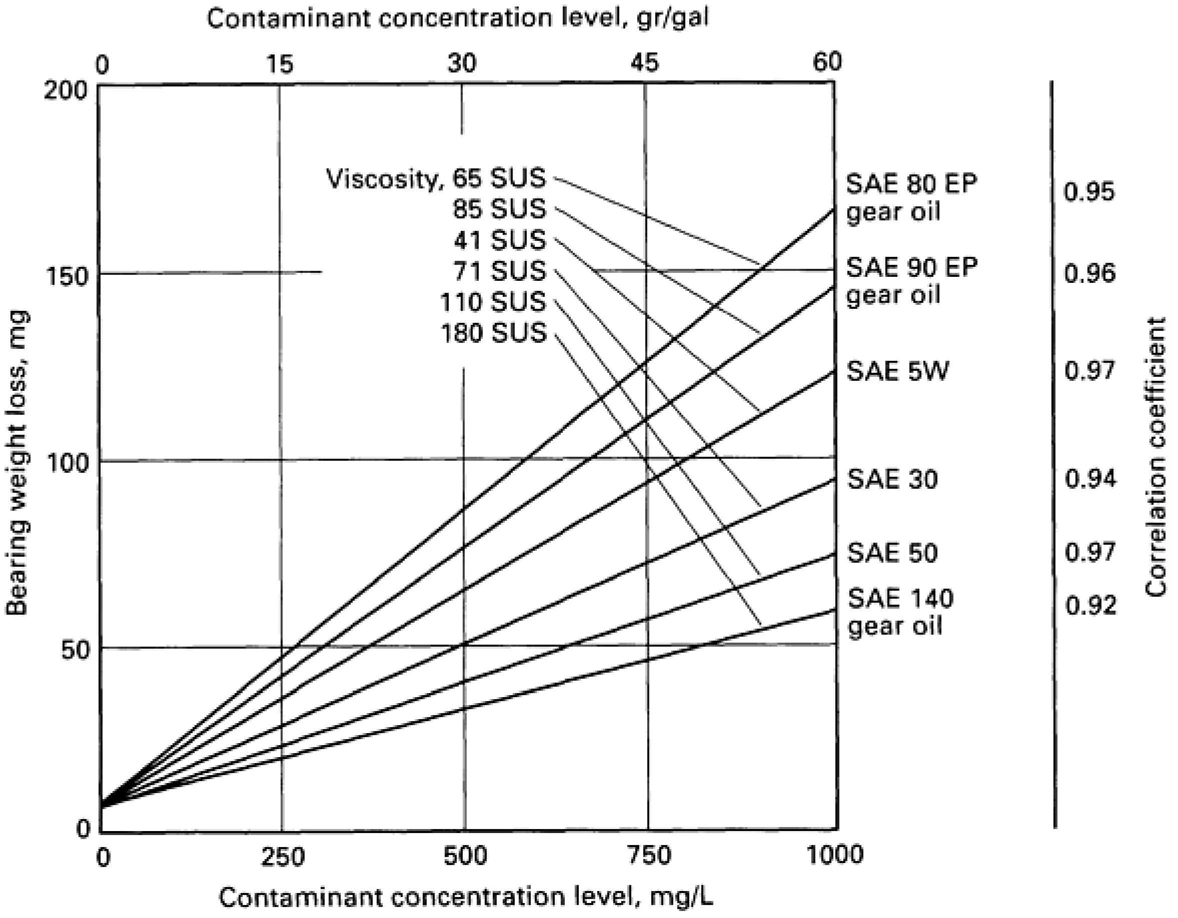

Fig. 15 Plot of bearing weight loss versus contaminant concentration level as a function of selected lubricant oils of varying viscocity. Test parameters: lubricant temperature of 90 to 100 °C (190 to 210 °F); contaminant, uncut silica dust; test duration, 10 h. Oil viscosity data are at temperature of 95 °C (200 °F)

There is also some indication from Table 10 that the extreme-pressure additive in an oil may lead to increased wear in the presence of debris. Abrasive wear can remove the oxide films normally present on bearing steel surfaces, and the chemical activity of the additive constituents (for example, sulfur) will attack the exposed surface and promote the increased wear.

Adhesive Wear

Under certain circumstances, bearing surfaces show evidence of adhesive wear. It may be observed under low lambda ratios, very often <0.3, combined with lower inadequate viscosity and higher temperatures.

Low-Speed Wear. Adhesive wear can occur under extremely low-speed conditions when adequate lubricant films cannot be formed and asperity interaction (probably multiple occurrences within a contact) leads to junction formation, deformation, and fracture. The adhesive wear manifests itself by the metal transfer, which, if small (down to microscopic in size) and somewhat isolated, may not grow but be limited as run-in. If it grows, the result is usually rough operation and erratic torque. If cages or rolling-element retainers are involved, bearing lock-up can finally occur.

High-Speed Wear. At the other extreme, under high-speed conditions, especially with centrifugal force influence, intermittent rolling-element lift-off can occur and skidding or extended sliding develops, which can lead to excessive heat generation and finally seizure. Standard bearing steels (Tables 1 and 2) are more susceptible to adhesive wear than the high-temperature steels because the high-temperature steels maintain hardness and strength to better resist the formation of localized microweld junctions within the contact. It is also possible that, at temperatures which exist at the microweld junctions, if certain EP additives are present in the lubricants, their activation may resist adhesive wear in bearing steel.

Some indication of the ranges within which adhesive wear may not occur is shown in a scuffing limit map such as that proposed in Ref 29.

Friction and Wear of Tool Steels

James L. Maloney III, Latrobe Steel Company

Introduction

TOOLS STEELS are carbon, alloy, and high-speed steels that can be hardened and tempered to high hardness and strength values. These steels are used when resistance to deformation, heat, and wear are necessary. Typical applications involve metalworking operations, such as cutting, shearing, and forming. However, tool steels are also used in other situations, such as pump impellers and cases where good resistance to wear is necessary.

Most tool steels are electric-furnace melted, refined in a secondary vessel, cast into ingots, and hot worked into final form. However, some are used as-cast and others are manufactured by:

- Atomizing the steel into powder with either gas or water
- Consolidating by sintering, pressing, or forging
- Finishing by hot working
- Heat treating (if in near-net shape)

All tool steels are heat treated after the tool is rough-machined by hardening (austenitizing and quenching into water, oil, or air, as appropriate) and tempering to obtain the requisite hardness and toughness for the tooling application.

The American Iron and Steel Institute (AISI) has developed a classification system for tool steels (Ref 1). The commonly used tool steels in each classification are shown in Table 1, whereas the relative abrasion resistance of various tool steels is shown in Fig. 1. Wear-related applications, in order of ascending abrasion resistance based on the AISI classification, are described below.

(a) All steels except group W contain 0.25 max Cu, 0.03 max P, and 0.03 max S; group W steels contain 0.20 max P, and 0.025 max S. Where specified, sulfur may be increased to 0.06 to 0.15% to improve machinability of group H, M, and T steels.

(b) Available in several carbon ranges.

(c) Contains free graphite in the microstructure.

(d) Optional.

(e) Specified carbon ranges are designated by suffix numbers.

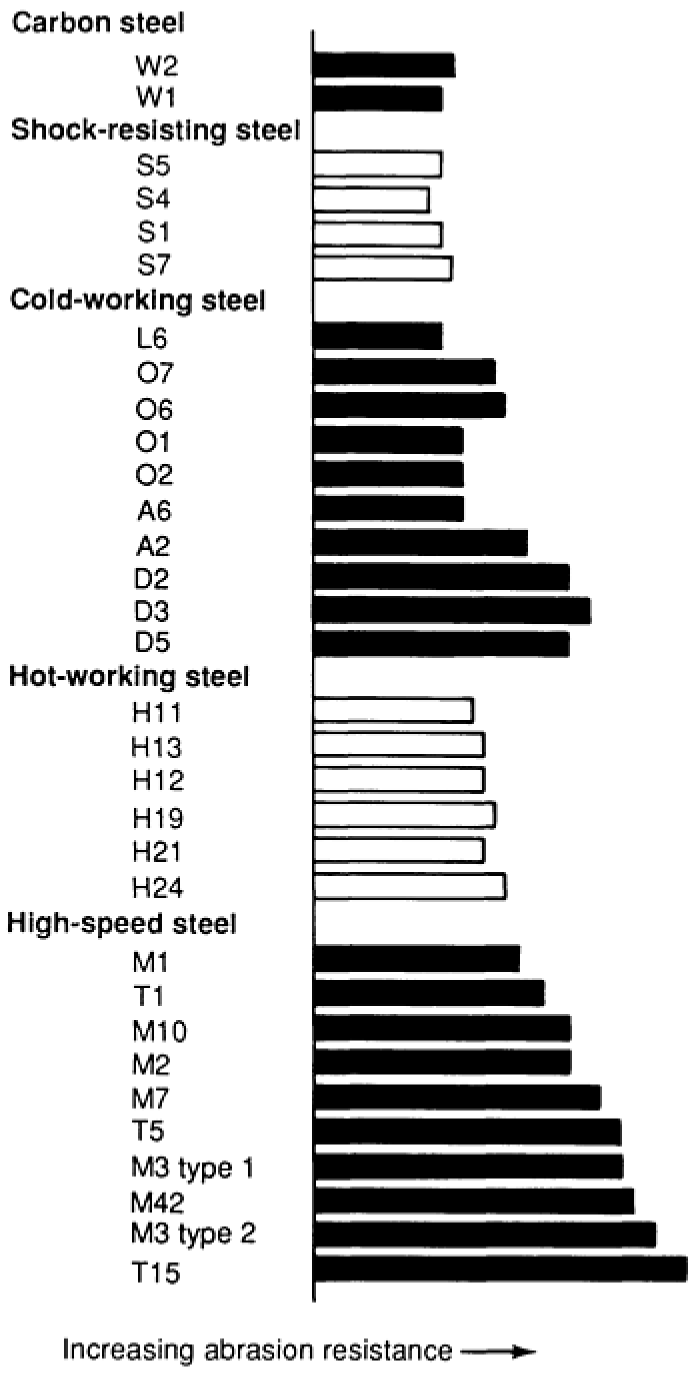

Fig. 1 Relative abrasion resistance of tool steels. Source: Ref 2

Water-hardening tool steels (Type W) contain carbon as the primary alloying element. Some grades of this type contain small amounts of either vanadium, for grain refinement, or chromium, for increased wear resistance. Although the relative wear resistance of these tool steels is low (Fig. 1), they are used in short-run wear applications where toughness is also required. Typical applications include files, woodworking tools, taps, reamers, drills, cold heading, and forming and blanking dies. These tools are heat treated to high surface hardness (HRC 59-64) before use. One of the highest-volume applications of water-hardening die steels is the coining of dies used to manufacture silverware and stainless dinnerware. The grades within this category are shallow hardening, so that when heat treated in section sizes thicker than 13 mm (0.5 in.), they have a hard case with a tough, lower-hardness core.

The abrasive wear resistance of these grades is directly related to their carbon content. As carbon content increases, so does hardness and wear resistance. This relationship is shown in Fig. 2, where linear wear resistance relative to a standard

material is plotted versus sample hardness for several levels of carbon in steel. This figure also demonstrates that abrasive wear resistance and material hardness are directly related.

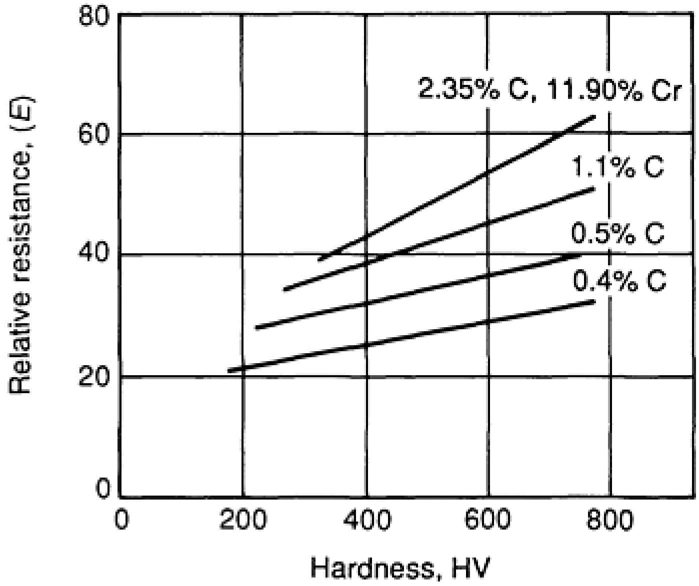

Fig. 2 Resistance to abrasive wear as function of both hardness and carbon content. Source: Ref 3

Several factors are important to the abrasion wear resistance of water-hardening tool steels: increased carbon content, increased surface hardness, and increased volume fraction of cementite. Of course, the first factor is related to both of the other factors.

Shock-resisting tool steels (Type S) have lower carbon contents than the water-hardening tool steels and are thus unable to achieve the same high hardness values. However, they are alloyed with manganese, silicon, and, sometimes, tungsten, chromium, or molybdenum to improve hardenability (depth of hardness). Vanadium sometimes is added to improve hardenability and to promote a fine grain size. Although the wear resistance of these tool materials is roughly equivalent to the water-hardening tool steels, they possess higher toughness properties. They are used in applications requiring shock resistance, such as chisels, hammers, punches, shear blades, stamps, and rivet sets.

The wear resistance of these shock-resisting steels is no longer a simple function of carbon content alone. Additions of chromium and molybdenum add not only to hardenability, but also contribute to increased wear abrasive resistance (Fig. 1). On the basis of carbon content and hardness alone, grade S5 should possess the highest wear resistance, but grades S1 and S7 both have somewhat higher wear resistance, because of their increased chromium and molybdenum contents.

Cold-work tool steels are described below in terms of three types.

Type A comprises medium-alloy, air-hardening materials intended for use at or near room temperature. Manganese, chromium, molybdenum, and vanadium are the major alloying elements that are used to promote deep hardening in these steels. Their high carbon content imparts good wear resistance in most applications, which typically include: blanking, coining, and other cold-forming tools, as well as molds, rolls, shear and slitter knives, and mandrels.

Type O comprises low-alloy steels that are hardened by oil quenching. The principal alloying elements are manganese, tungsten, molybdenum, and chromium. Applications include dies for blanking, coining, drawing, or forming, as well as gages, cams, plastic molds, shear blades, and machine ways. The oil-hardening cold-work steels are intended for room-temperature applications and rely on high carbon contents and undissolved carbides for their wear resistance.

Type D steels have high carbon and chromium contents and are deep hardening. All of the commonly used grades, except D3, contain 1 wt% molybdenum, and some contain either vanadium or cobalt. The wear resistance of these steels is exceptional and increases with increasing carbon and vanadium content. Popular applications include blanking, cold forming, lamination, and drawing dies, gages, punches, rolls, slitter and shear knives, and thread-rolling dies.

Hot-work tool steels (Type H) are medium-carbon steels with additional alloying elements that help maintain hardness and wear resistance at higher temperatures. All grades contain chromium; grades H20 to H39 contain tungsten, and H42 contains 5 wt% molybdenum. All of the hot-work steels are deeply hardenable.

Typical applications involve elevated-temperature use, as in forging and extrusion dies, bolsters, dummy blocks, gripper and hot heading dies, mandrels, punches, and piercing tools. The tungsten (H20 to H39) and molybdenum (H40 to H59) types are used in the highest-temperature applications, where resistance to softening is of the greatest importance.

High-speed tool steels are described below in terms of two types.

Type M steels have high carbon contents, with molybdenum as the major alloying element. Other alloying elements include tungsten, chromium, vanadium, and cobalt. These steels reach exceptionally high hardness after heat treatment and can maintain that hardness at elevated temperatures.

Typical applications involve metal cutting (specifically, broaches, chasers, taps, reamers, drills, end mills, hobs, lathe tools, and saws) and metalworking (punches, thread-rolling dies, cold-heading dies, and blanking dies). Woodworking applications, as well as bearing and pump components, are also candidates for high-speed tool steels.

Type T steels also have high carbon contents, with tungsten as the primary alloying element. Chromium and vanadium are present as alloying elements in all Type T steels; most also contain cobalt. These steels are used in applications similar to those that use Type M. However, the tungsten types tend to be less tough, more resistant to heat, and slightly higher in abrasion resistance.

Metallurgical Aspects of Tool Steel Wear

There are four basic mechanisms of tool steel wear: abrasion, adhesion, corrosion, and contact fatigue wear. Tool steels are most often used in metalworking processes, in which the effects of the different wear mechanisms are often combined.

Adhesive wear is usually the life-limiting wear mechanism in dry metal-forming operations. Because lubrication is very effective in alleviating adhesive wear, abrasive wear often becomes the life-limiting factor. However, wear is usually a complex mixture of the differing mechanisms. Therefore, production experience in tool steel, lubrication, and coating combinations, as well as experimentation, are the means for choosing the ideal tool steel for the application.

Abrasive wear is experienced whenever a hard phase is rubbed against tool steel. The hard phase can be embedded in a softer phase, such as oxide inclusions in steel or aluminum, or it can be in a liquid carrier, such as the grinding dust carried onto tool steel guides by the lubrication flow or the contaminants in fuel or oil that is to be pumped.

As previously discussed and shown in Fig. 2, the abrasion resistance of carbon tool steels (W type) is directly related to the hardness and carbon content of the steel. Other work by Larsen-Basse (Ref 4) shows that wear resistance also has a linear relationship with the volume fraction of cementite (Fe_3C, iron carbide), as illustrated in Fig. 3.

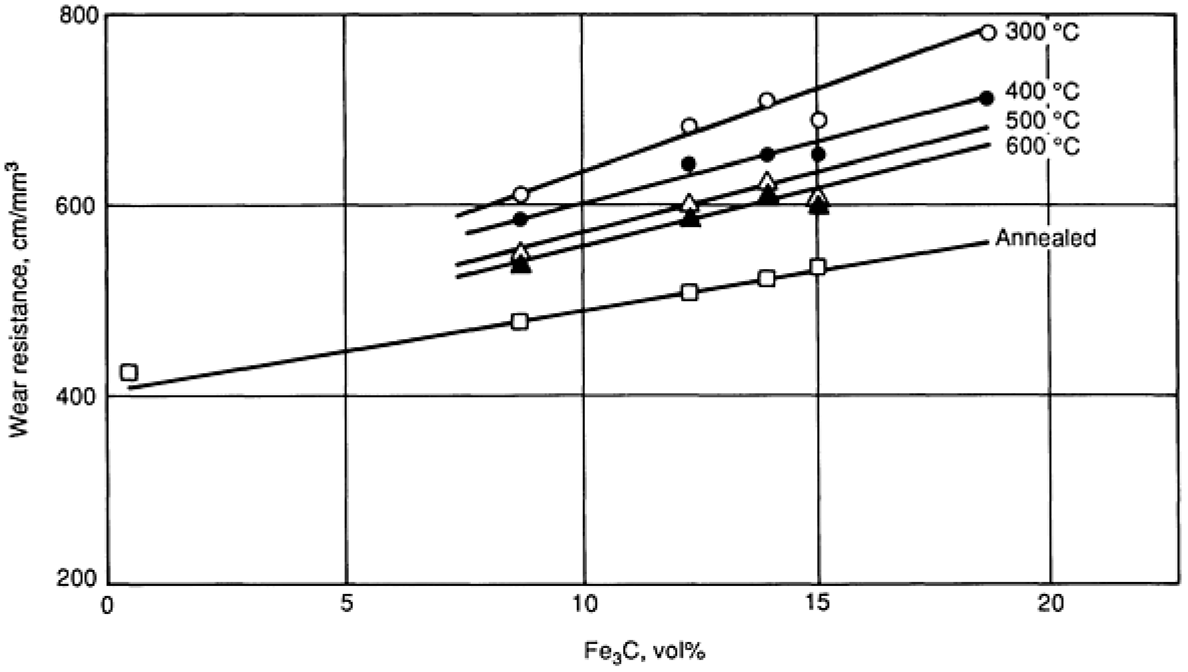

Fig. 3 Abrasion resistance of hardened and tempered carbon steels as function of volume fraction of cementite. Temperatures shown indicate tempering temperature; hardness decreases as tempering temperature increases. Source: Ref 4

Abrasion resistance was defined in Ref 4 as the sample sliding distance divided by metal removal by dry 400-grit silicon carbide sandpaper. The different tempering temperatures plotted also show the influence of hardness on wear resistance; hardness increases with decreased tempering temperature.

A detailed study of the dry abrasive wear of tool steels was conducted by Budinski (Ref 5). His assessment of the data showed very good correlation with a structural parameter, *A*, which equals the primary carbide size, multiplied by the volume fraction of carbides, multiplied by carbide hardness. The data are shown in Fig. 4. The implication of this finding is that the most abrasion-resistant tool steel will have a large volume fraction of large, hard carbides.

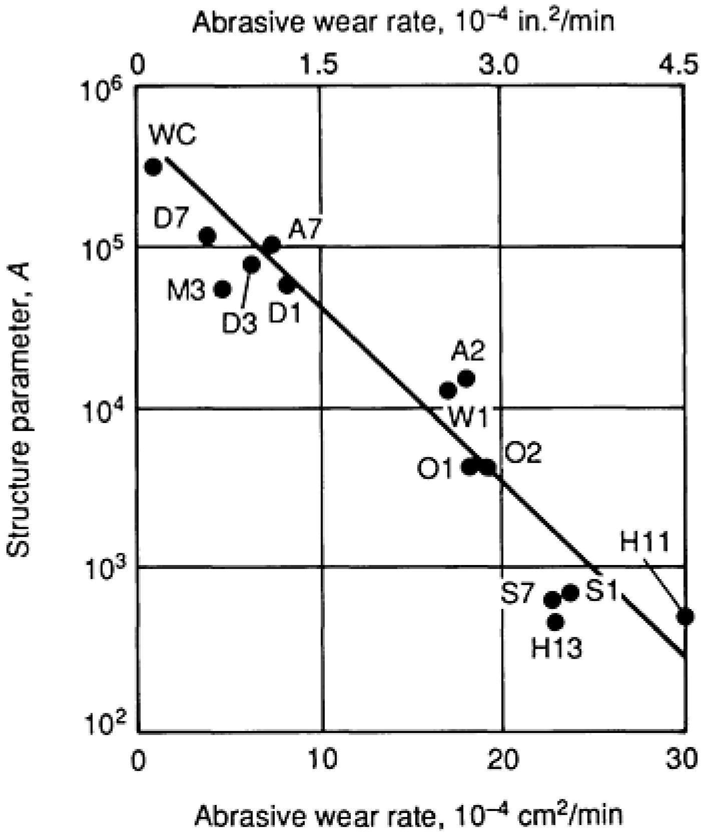

Fig. 4 Abrasion resistance of tool steels versus a structural parameter (defined in text). Source: Ref 5

Care must be used in committing these results to steelmaking practice. Most wear is metal-to-metal; therefore, abrasion is not the only mechanism operative. In addition, large carbides can be torn from the tool steel matrix and will enhance tool steel wear by adding abrasive carbide particles to the wear debris (Ref 6). This effect can also occur if tool steels are overtempered (Ref 7).

Adhesive wear between tool steel and workpiece can result when direct contact occurs because of lubricant breakdown, high pressures, or process design. This type of wear is due to the cold welding of microscopic asperities between the tool and the workpiece. The environment also has an effect. Generally, adhesive wear becomes more severe as oxygen content decreases (for example, sliding in a vacuum), because no oxide layer can form.

Metallurgical factors that reportedly decrease the adhesive wear of tool steels include higher tool steel hardness at temperature (hot hardness), the built-in lubricity of graphitic tool steels (Types O6 and A10), small grain size (Ref 8), a large volume fraction of primary carbides (Ref 9), and small primary carbide size (Ref 8). Most of these factors have been established from empirical data. However, it is not at all clear that they control adhesive wear in all cases.

For example, Budinski has evaluated the wear between unlubricated tool steel and hardened 440C steel, as well as between tool steel and annealed 1020 steel. He found no correlation between tool steel wear and certain factors, specifically carbide size, carbon content, carbide volume fraction, total alloy content, and hardness, nor did he find a structural parameter combining primary carbide size, carbide volume fraction, and hardness (Ref 5).

An extreme case of adhesive wear, sometimes called continuous wear, occurs in high-speed tool steels used in demanding metal-cutting applications. Tool temperatures at the tip and in the wear crater can approach 700 °C (1300 °F), and direct contact with the chip causes alloying elements (usually carbon and chromium) to diffuse out of the tool steel and into the chip. Adhesive wear of this severity is often called seizure, or galling. The solution is to reduce the cutting speed, coat the tool, or improve the lubrication and cooling.

Corrosive wear is usually not a major cause of excessive tool steel wear, but it can become the most important wear mechanism at high temperatures or during plastics processing. Wear proceeds by the corrosion of fresh, exposed tool steel, followed by rupture of the corrosion film by the workpiece and corrosion of the newly exposed surface. This form of wear can usually be controlled by proper lubrication, higher-chromium tool steels, or coatings.

Contact fatigue wear is caused by repeated sliding or rolling of one component over another, which leads to spalling or microcracking. This type of wear often manifests itself as cutting or punch edge chipping. Surface fatigue wear by rolling members is the subject of several other articles in this Volume and is therefore not addressed here.

Improved toughness and higher hardness are the most common metallurgical solutions to contact fatigue wear. These two properties have a strong inverse influence on each other, and care must be taken to avoid creating a larger problem when increasing either. One approach that improves toughness without influencing hardness is to decrease the carbide size by substituting a powder metallurgy product (Ref 10). Another approach is to lower the hardening (austenitizing) temperature.

Lubrication of Tool Steels

Several considerations are involved in the selection of lubrication systems for tool steel applications. The lubricant should ideally provide a continuous layer between the tool steel and workpiece in order to:

- Reduce friction and adhesive wear
- Bond to the tool steel to prevent gouging and die pickup on the workpiece
- Flush metalworking debris away from the tool steel-workpiece interface
- Extract heat away from the tool steel

Because lubrication systems are highly dependent on the operation being conducted, this discussion focuses on metalworking examples, rather than tool steel types. The coefficient of friction in metalworking processes is influenced by many variables. The values presented here only give an approximate magnitude and are just intended to illustrate the effect of lubrication on friction. Therefore, they should be used with caution.

Sheet Metal Forming. The primary function of lubrication in press forming is to prevent galling (tool material pickup). A secondary function is to reduce die wear through abrasive and chemical wear mechanisms. Light press forming of most metals requires only light mineral oil or soap lubrication to prevent die wear. More severe conditions, experienced when forming copper-, iron-, and nickel-base alloys, usually require liquid lubrication using either mineral oils with extreme-pressure (EP) additives (such as sulfur and chlorine) or zinc stearate soaps in order to prevent galling. The coefficient of friction experienced in deep drawing and stretch forming is reduced as the viscosity of the lubricant increases (Ref 11, 12, 13), with an attendant reduction in the surface quality of the formed part (Ref 11).

Solid-film lubricants in the form of polyethylene (PE), polyvinylchloride (PVC), and polytetrafluoroethylene (PTFE), which are applied to the workpiece as a powder, coating, or solid sheet, also give adequate protection against adhesive wear. Extreme conditions encountered when press forming iron- and nickel-base alloys require a phosphate-coated product and soap lubrication to prevent excessive die wear. Tin-coated steel, with additional liquid lubrication of mineral oil or emulsions to cool the die, has also been successful in preventing die pickup in severe press-forming applications.

Moderate-to-severe forming of aluminum and magnesium alloys is normally accomplished with solid film soap or wax lubrication. The forming of titanium alloys always requires at least an EP oil; as the forming becomes more severe, wax or soap lubrication is preferred. Warm forming of magnesium and titanium alloys can best be accomplished with either organic- or water-based colloidal graphite coatings of the workpiece.

Hot extrusion, particularly at higher temperatures, is an extremely demanding application for tool steels. Both adhesive and abrasive wear, in addition to thermal fatigue and high temperatures, make the choice of lubrication system critical to success. A good lubrication system should act as thermal insulation between the extrusion billet and the tool steel, promote easy sliding by providing a continuous film between the billet and tool steel, and should be chemically inert to both the extrusion tooling and billet. The coefficient of friction in hot extrusion varies between 0.015 and 0.2, which underscores the diversity of this process (Ref 14).

Lubrication systems for hot extrusion are extremely varied, because extrusion must be either totally unlubricated or fully lubricated to achieve good extrusion performance and the reduction of surface defects. The range of temperatures employed in extrusion also creates a challenge in lubrication technology. Extrusion that uses bridge, spider, or porthole dies must be carefully accomplished to ensure that no lubricant is entrapped in the pressure-welded interface created during extrusion. For this reason, and to prevent surface and subsurface entrapment of lubricant, most aluminum extrusion is conducted without lubrication.

The major problems in unlubricated aluminum extrusion are die pickup and wear. Internal water cooling of the die and carefully controlling extrusion rates to avoid excessive die temperatures are frequently used to prevent sticking and die wear. Die pickup, in this case, is primarily caused by oxygen in the form of either aluminum oxide or iron oxide. The wear resistance of the die can be improved by preventing oxygen contact with the die by (Ref 15):

- Extruding low-oxygen billet material
- Mechanically removing surface oxide from the billet by machining or shot blasting
- Maintaining an oxygen-free atmosphere around the die by shrouding with inert gas
- Cleaning or surface dressing the die between pushes to prevent die oxidation when the die is not in contact with the extruded metal
- Leaving the tail end of the extrusion piece in the die, thereby preventing oxidation of the die

Hot extrusion of copper alloys is simplified by the fact that the copper oxide formed during preheating is a good lubricant. Sometimes, the oxide lubrication is aided by spraying an oil-graphite mixture onto the container walls, mandrel, and die face. However, the oxide formed on brass alloys does not have good lubricity. Brass and hard copper alloys are therefore often extruded using glass lubrication.

For titanium, refractory metals, and iron- and nickel-base alloy extrusion, the lubrication is either graphite in oil or fat (for short pieces) or glass (Ref 16). The glass lubricant is usually a basalt mixed with borosilicate glass.

A mild steel can is sometimes welded around billets of highly alloyed stainless steel and nickel-base alloys to act as both lubricant and friction-reducing agent by preventing adhesion between the die and the extrusion billet. This process, known as either canning or jacketing, not only improves the lubrication at the interface between the tool steel die and extrusion billet, but also acts as a barrier to oxidation of the billet, thereby reducing abrasive wear of the die by hard oxide particles. Sometimes, glass lubrication is used to augment the lubrication provided by the can.

Other materials are also used for the can. The important parameters in choosing a can material are chemical inertness to both the extrusion billet and the die, lack of adhesion to the die, and a yield strength at temperature that is from one-third to one-half that of the extrusion billet yield strength. Examples are copper tubing and pure aluminum tubing over hard aluminum alloys.

Hot forging, particularly the closed-die practice, is also a very demanding application for tool steels. Lubricants used in these situations have several functions:

- Reduce friction to produce well-filled forgings at the lowest power requirements possible
- Insulate the tool steel dies from the hot work-piece
- Provide a barrier between the die and workpiece to prevent chemical attack
- Prevent erosion (abrasion) of the tool steel die
- Aid in releasing the completed forging from the die

Dry friction coefficients for uniaxial compression (upsetting) are about 0.2 for aluminum and steel and about 0.1 for copper and brass. Lubrication reduces these values to a range from 0.05 to 0.07 (Ref 17).

The most commonly used hot forging lubricants are graphite suspensions in water, grease, or oil, which are applied by spraying or swabbing. An even spray coating is preferred. Other common hot forging lubricants are sawdust (the first lubricant used); chloride salts, such as NaCl or $BaCl_2$; solid lubricants, such as talc, mica, vermiculite, white lead, and alumina; and metal films deposited on the workpiece.

Forging temperature has a pronounced influence on the type of lubrication used in forging. Most organic-based lubricants break down at temperatures above approximately 200 °C (390 °F), although aluminum stearate is apparently useful up to a temperature of about 400 °C (750 °F). Much hot forging work is done at temperatures that exceed 1000 °C (1830 °F). The only successful lubricants at these temperatures are graphite, glasses, and metallic oxides, such as copper oxide.

Cutting. The use of proper lubrication in cutting with tool steels is critical to good tool life and the prevention of wear. Cutting fluids perform several functions in metal cutting operations:

- Cooling of tool and workpiece
- Lubricating to reduce friction and adhesive wear
- Reducing built-up edge
- Flushing away the chips generated
- Protecting both the tool and workpiece from corrosion

The most important consideration is the cooling aspect, because the tool-workpiece interface temperature can rise to temperatures that exceed 600 °C (1110 °F), which causes tool softening and greatly accelerates tool wear. Proper cooling can reduce tool wear by approximately 33% (Ref 18).

The coefficient of friction in cutting depends on the material being cut, the lubricant, and, to a much lesser extent, the cutting tool steel. At low cutting speeds, the coefficient of friction appears to be a function of the number of carbon atoms per unit volume of the cutting fluid. An increasing carbon content in the lubricant results in a decreased friction coefficient. Using proper lubrication, friction can be reduced by 60% when cutting aluminum, 84% when cutting copper, and approximately 35% when cutting steel and stainless steel. Friction coefficient values are reportedly between 0.25 and 0.55 (Ref 19).

Several types of fluids are used in cutting operations. The most common are cutting oils, which are usually mineral oils or water-based miscible oils. Some synthetic fluids, gases, and solid lubricants are also used. The mineral-oil-based fluids have excellent lubricating and oxidation (rust) prevention properties. The water-based oils have better cooling properties than the mineral-oil-based products, in general, and thus are often used in high-speed machining operations.

Chemical fluids are good coolants, and some are also useful as lubricants. These fluids are chemical solutions of various inorganics dissolved in water. Although most liquid cutting fluids are applied by flooding both the tool and the workpiece, mist application is also used when visibility of the cutting operation is desired.

Air, argon, helium, and nitrogen are some common gases that are used as cutting fluids when either contamination of the workpiece or a clear view of the cutting process is necessary. Obviously, the cheapest and most common gaseous form of cutting fluid is air. Other gases with boiling points below room temperature, such as CO_2 and fluorinated hydrocarbons, are sometimes used when extra cooling is needed.

Solid lubricants are most commonly available in the form of greases, waxes, graphite compounds, molybdenum disulfide compounds, and soaps. They are most often applied by brushing in low-speed operations, such as hand tapping and reaming.

Surface Treatments

Most surface treatments are employed to increase surface hardness and/or wear resistance, minimize adhesion (reduce friction), or improve the corrosion resistance of the tool steel base.

Carburizing. The processes of case hardening and carburizing are of limited use in tool steel applications, because of the relatively high carbon contents of the tool steels. Carburizing can be accomplished in many ways, and essentially consists of heating the final machined tool into the austenite region in the presence of carbonaceous solids, liquids, or gases.

Low-carbon plastic mold steels (P type) are often carburized after hubbing or machining of the cavity in the mold. In this application, the tool steel is intentionally lean in carbon content to improved hubbing or machining, and must be carburized in order to have sufficient surface hardness for the end use.

Nitriding is a frequently used surface treatment that increases surface hardness, adds to the corrosion resistance of the tool, and reduces friction. Basically, the process involves heating the finished tool in the presence of a nitrogen-containing liquid or gas and allowing nitrogen to diffuse into the tool. Gas nitriding is usually accomplished at a lower temperature (about 527 °C, or 980 °F) and longer time (10 to 90 h) than liquid nitriding, which occurs at temperatures ranging from 538 to 552 °C (1000 to 1025 °F) for 2 to 4 h. A nitrided depth that ranges from 13 to 76 m (0.0005 to 0.003 in.) is desired.

Because of decreased wear and die pickup, cold-extrusion punches experience a two to three-fold improvement in life. Nitriding is often used whenever mold wash is a problem in the die casting of zinc or aluminum alloys. Galling of sheet metal working dies can be alleviated by nitriding these dies before use.

Steels that will be nitrided should contain one or more of the nitride-forming elements (chromium, vanadium, or aluminum) in order to prevent the easy spalling and chipping that results when iron nitride is formed. Commonly nitrided tool steels include H11, H12, H13, A2, O2, and the high-speed tool steels.

Ion or plasma nitriding has many of the same characteristics of liquid or gas nitriding. This process relies on a nitrogen gas being ionized by glow discharge conditions between the tool (cathode) and the furnace wall or shield (anode). The primary advantages are the reductions in time and temperature, which save money and reduce the distortion and softening of prehardened tools. Usually, treatment times vary between 0.5 and 36 h.

Oxidation is a well-established process used for high-speed steel-cutting tools. Increases in tool life of up to 100% are mostly due to a decrease in friction, because of the hard oxide coating and the ability of the porous oxide to entrap lubricant and draw it to the tool-work-piece interface (Ref 20). Steam oxidation of a finished tool is accomplished either by exposure to steam at a temperature of about 566 °C (1050 °F) or by treating in liquid sodium hydroxide and sodium nitrate salts at approximately 140 °C (285 °F) for periods of time ranging from 5 to 20 min. These treatments result in a black oxidized layer that is less than m (0.0002 in.) thick and will not peel, chip, nor crack, even when the tool is bent or cut.

Boriding. In this process, boron atoms from a solid, liquid, gas, or plasma atmosphere surrounding the finished part are diffused into the surface, creating a hard, wear-resistant iron boride layer. Metal-to-metal wear testing demonstrated a three-fold improvement in wear resistance of borided O1 and O2 tool steels and over a two-fold increase in A2 tool steel (Ref 21). Borided A2 tool steel showed twice the life of uncoated O2 tool steel in a deep-drawing operation in which low-carbon steel cups were manufactured (Ref 21). An H13 roller designed to flange milk cans was borided and produced three times as many cans before it wore out (Ref 22).

Boriding takes place at temperatures as low as 600 °C (1100 °F), but usual practice involves a period from 1 to 6 h at temperatures from 800 to 900 °C (1470 to 1650 °F) (Ref 21, 22). The resultant layer is between 13 and 130 m (0.0005 and 0.005 in.), and tends to be dull because of the microroughness of the surface. The high process temperature requires that the boron treatment act as the austenitization step, or else the process must be followed by reaustenitization. This necessarily limits the process to applications where tolerances of about 25 m (0.001 in.) can be tolerated.

Plating. Three different kinds of plating are used on tool steels. Cadmium plating is used for appearance purposes and to reduce corrosion of the tool. It also has some usefulness in preventing adhesion. Nickel plating is commonly used for appearance purposes and to prevent corrosion.

The most commonly practiced tool steel plating process is hard chromium plating. Plating thickness varies between 2 and 13 m (0.0001 and 0.0005 in.) and, because it is very hard, it prolongs life by increasing abrasive wear resistance. More important than plating hardness is its very low friction coefficient, which effectively prevents adhesive wear.

However, hard chromium plating is not without problems. Tool steels may be hydrogen embrittled when plated, and the plating has a tendency to spall and flake. These wear debris can actually accelerate abrasive wear.

Chemical vapor deposition (CVD), a process conducted in a vacuum chamber, relies on a deposition from reacted gas onto the tool steel surface. Many different materials can be used as coatings. Chromium, Al_2O_3, TiC, CrC, Fe_4N, and TiN are commonly used, and other materials are being studied. This process utilized high temperatures, usually above 800 °C (1472 °F), which means that tool steels must be tempered after the CVD coating is applied. The most popular wear-resistant coatings are TiC and TiN, which are used to coat high-speed, cold-work die and hot-work die tool steels. These coatings commonly range in thickness from 2 to 20 m (0.0001 to 0.001 in.). Using CVD coating with TiC and TiN, the

primary mechanism of wear reduction is the extremely high hardness, which leads to excellent abrasion resistance, although some decrease in friction coefficient can often be realized. The chlorine content of the coating must carefully be maintained at a level below 5% to avoid degradation of the wear resistance (Ref 23).

Tool steels that can be successfully CVD coated include the AISI A, S, D, H, M, and T steel types. The lower-alloyed S type and all of the W and O types are either very difficult or impossible to properly coat, because of their low austenitization temperatures.

Physical vapor deposition (PVD), which is also conducted in a vacuum chamber, can be accomplished in several different ways. The process relies on plasma-aided precipitation of either TiC or TiN onto tool steel at temperatures ranging from 200 to 550 °C (400 to 1025 °F) (Ref 23). This temperature range is much more suitable for the coating of high-speed tool steels than the temperatures required for CVD.

Tool steel wear is reduced in about the same proportions (2 to 6 times less wear), whether the TiC or TiN is applied by CVD or PVD. TiN coatings on H13 pins reduced the friction coefficient in pin-on-disk tests from 0.7 to less than 0.2 (Ref 24). Modified ASTM G65-10 to abrasive wear testing of D3 steel showed that wear of the TiN-coated samples was between 4 and 23% of the uncoated samples, depending on their initial surface roughness (Ref 24). This result led Sundquist *et al.* to propose that increases in tool life that are due to TiN coating can only be expected when the surface roughness is less than the coating thickness (Ref 24).

Friction and Wear of Sliding Bearing Materials

George R. Kingsbury, Glacier Vandervell Inc.

Introduction

A SLIDING BEARING (plain bearing) is a machine element designed to transmit loads or reaction forces to a shaft that rotates relative to the bearing. Journal bearings are cylindrical (full cylinders or segments of cylinders) and are used when the load or reaction force is essentially radial (that is, perpendicular to the axis of the shaft). Thrust bearings are ring-shaped (full rings or segments of rings) and are used when the load or reaction force is parallel to the direction of the shaft axis. Both radial and axial loads can be accommodated by flange bearings, which are journal bearings constructed with one or two integral thrust bearing surfaces. The sliding movement of the shaft surface or thrust-collar surface relative to the bearing surface is characteristic of all plain bearings. In many applications, plain bearings offer advantages over rolling-contact bearings--such as lower cost, smaller space requirements, the ability to operate with marginal lubricants, resistance to corrosion, and the ability to sustain high specific loads.

Plain-bearing principles have been employed in rotating mechanical devices since about 3000 B.C. However, the first use of a metal alloy because of its special properties for bearing service applications was probably Isaac Babbitt's adaptation of a pewter composition in 1839. The design and manufacture of metallic plain bearings as separate machinery components that are mechanically assembled in precisely machined housings are recent developments. Until early in the twentieth century, machinery bearings were machined from massive tin alloy or bronze castings, or were made by pouring molten babbitt metal into cast or machined holes in iron or steel machine members. The final bearing bore was then produced by cutting away excess material, leaving the hole with a relatively thick lining of bearing metal that was more or less completely bonded to the housing.

Since the 1930s, bearing developments have proliferated with respect to materials and material systems, mechanical design, and manufacturing technology. Single-metal cast-in-place bearings have been largely supplanted by replaceable-insert bearings made from multilayer laminated metals; as a result, the mechanical design of bearings has become an increasingly refined engineering specialty. Manufacturing technology has evolved into a remarkably sophisticated complex of metallurgical, chemical, and mechanical processes. The scale of manufacturing operations ranges from the production of small lots by job-shop methods to the extremely high-volume mass production of automotive bearings.

Sliding bearings are commonly designated by terms that describe their application, such as:

- Connecting-rod bearing
- Main bearing
- Camshaft bearing or bushing
- Electric motor shaft bushing
- Countershaft thrust washer

With respect to size, sliding bearings are frequently classified as either thin wall (that is, thinner than ~5 mm, or 0.2 in.) or heavy wall. In general, bearings with diameters >150 mm (>6 in.) are considered to be in the heavy-wall class.

Configurations can be further described as half round, full round, flanged, or washer. The Society of Automotive Engineers (SAE) standards classify thin-wall bearings into three groups:

- Sleeve-type half bearings
- Split-type bushings
- Thrust washers

Such bearings are almost always produced by high-speed forming and machining processes from materials in flat strip form, and the terms "strip-type bearing" and "sheet-metal bearing" are occasionally used to designate these components.

Heavy-wall bearings are manufactured in relatively small lots (that is, from one to a few thousand pieces) by more conventional machine shop manufacturing processes. Starting materials can be in the form of flat slabs or tubes; components made from these product forms are sometimes designated as "slab bearings" and "shell-cast bearings," respectively.

Sliding bearings are also frequently classified according to material construction, as single-metal (solid), bimetal (two-layer), or trimetal (three-layer) bearings. These terms refer to the number of principal functional layers that are used. Each one of these types of construction is in widespread commercial use and in a wide variety of applications. The use of two or three separate layers provides a means for developing property combinations that cannot be obtained with single-metal bearings.

From the standpoint of bearing material design and selection, some or all of the following wear damage mechanisms must be considered:

- Surface fatigue wear
- Abrasive wear
- Adhesive wear
- Erosive wear
- Corrosion

Typical examples of damage caused by these processes are shown in Fig. 1.

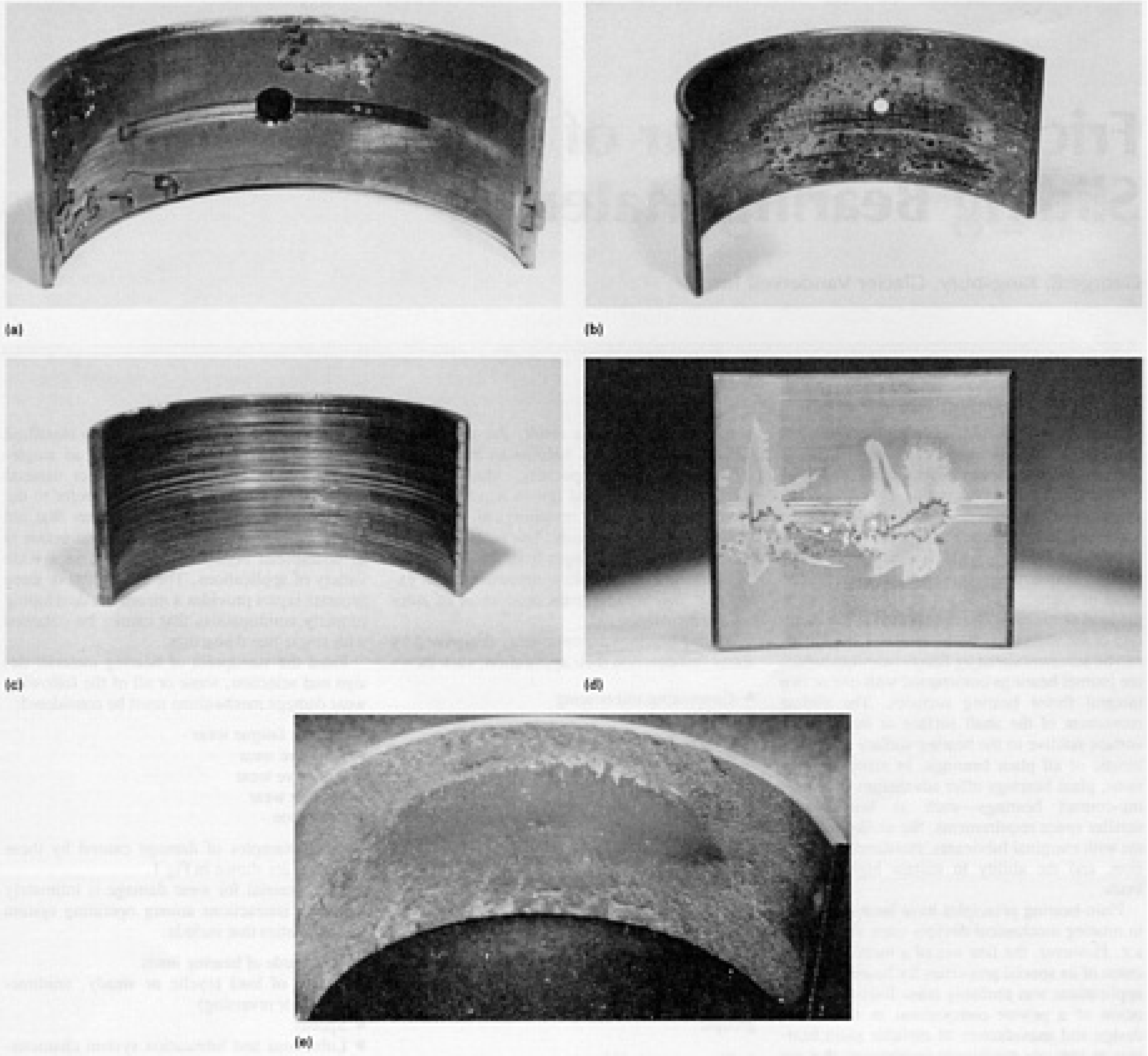

Fig. 1 Typical damage in sliding bearings caused by different wear processes. (a) Surface fatigue. (b) Abrasive wear. (c) Adhesive wear (scoring). (d) Erosive wear (cavitation). (e) Corrosion

The potential for wear damage is intimately linked to interactions among operating system characteristics that include:

- Magnitude of bearing loads
- Nature of load (cyclic or steady, unidirectional or reversing)
- Speeds
- Lubricants and lubrication system characteristics
- Lubricant cleanliness and filtration
- Operating temperatures
- Counterface (shaft) material and finish
- Alignment and rigidity
- Life expectancy

Additional information is available in the article "Friction and Wear of Sliding Bearings" in this Volume.

Properties of Bearing Materials

Surface and Bulk Properties. The conditions under which plain bearings must operate and the wide ranges over which these conditions can vary lead to concern about two kinds of bearing material properties: surface properties (those associated with the bearing surface and immediate subsurface layers) and bulk properties.

Conventional engineering definitions of materials properties do not adequately describe the distinctive properties that are needed in materials for sliding bearings. Table 1 lists some of the more important relationships between bearing material properties and wear damage mechanisms.

Table 1 Influence of bearing material properties on damage mechanisms

Bearing material property	Damage mechanisms counteracted	Causes
Compatibility	Adhesive wear	Asperity contact, surface roughness, inadequate oil film
Conformability	Adhesive wear, surface fatigue wear	Misalignment, edge loading, faulty assembly, geometric errors
Embeddability	Abrasive wear, adhesive wear	Dirt particles in oil, scoring
Fatigue strength	Surface fatigue wear	Excessive dynamic load, localized overload (for example, misalignment)
Hardness	Extrusion, erosive wear	Overheating, excessive load, cavitation effects
Corrosion resistance	Corrosive wear	Lubricant deterioration (overheating), lubricant contamination (water, fuel, refrigerant, combustion products)

Compatibility can be regarded as a purely surface characteristic. Conformability and embeddability involve the surface and immediate subsurface, and are strongly related to the bulk properties of strength and hardness. The other characteristics relate principally to bulk properties.

Measurement and Testing. Of the six characteristics listed in Table 1, only hardness can be measured satisfactorily by standard laboratory test methods. Many special dynamic test rigs and test methods have been developed by the plain bearing industry to evaluate and to measure the other characteristics and their interactions. Most of these testing systems are designed to subject specimen bearings to operating conditions that are qualitatively similar to the conditions of intended service, but quantitatively more severe with respect to one or several key parameters, such as:

- Magnitude of load
- Surface speed
- Operating temperature
- Lubricant supply
- Lubricant cleanliness

Figure 2 shows two different kinds of machines that are widely used to test engine crankshaft bearing specimens. Accelerated fatigue strength tests conducted in these machines can produce failures in $<10\%$ of the normal bearing life in a test engine.

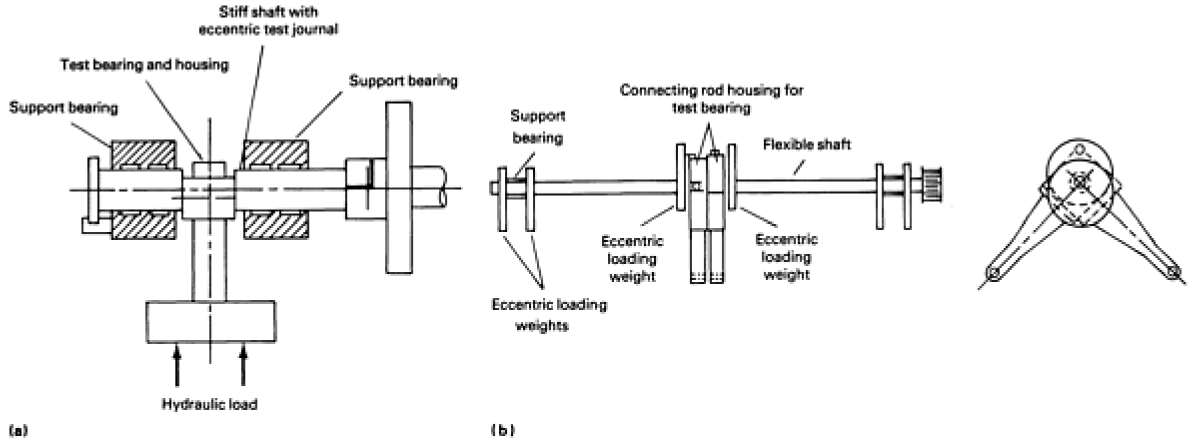

Fig. 2 Schematics showing key components of two types of engine bearing test machines. (a) "Sapphire" hydraulically loaded machine. (b) Front (left) and side (right) views of Underwood centrifugally loaded machine

Although much useful information has been developed through laboratory rig testing, it still is often necessary to test bearing materials and designs in full-size operating machines in order to clearly establish their overall suitability. Such testing is necessarily expensive and time-consuming. It should be undertaken only after careful study both of the conditions under which the bearing will operate and of prior experience in similar applications.

An appreciation of the relative importance of the various bearing material characteristics in the application at hand and an understanding of the trade-offs that are available usually will limit the viable choices to a manageable number. Full-scale bearing tests will then serve more for confirmation of the validity of design and material selections than for the exploration of design and material variables.

Compatibility. Compatibility is an antiseizure/antiscore characteristic that relates principally to the ease with which the bearing material surface will adhere or weld to a steel or iron journal surface under the influence of pressure and heat, and in the absence of a lubricant or some other intervening surface film. Some potential for scoring and seizure exists under all boundary and thin-film lubrication conditions.

Elemental metals that exhibit good compatibility with ferrous journal surfaces are all b-subgroup metals, with effective atomic radii substantially greater than that of iron. Only seven of these metals are commercially significant: silver, cadmium, indium, tin, antimony, lead, and bismuth. Of these, tin and lead offer the most attractive combinations of cost, availability, and engineering properties. Both metals are widely employed in bearing alloys because of their contributions to compatibility--either as the alloy base as in lead and tin babbitts, or as major alloy constituents as in leaded bronzes and aluminum-tin alloys.

Useful compatibility with steel is also exhibited by many nonmetals, including synthetic resins, carbon (if iron is in α phase), cemented carbides, intermetallic compounds, and ceramics. For all of these materials, compatibility probably can be attributed to a substantial lack of unsatisfied surface-atom force fields.

Conformability and Embeddability versus Hardness and Fatigue Strength. Both conformability and embeddability depend on the yielding and the plastic flow of the bearing material under load. Thus, it is not surprising that soft, weak, low-modulus metals such as tin and lead exhibit the best conformability and embeddability. Conversely, high fatigue strength is exhibited by harder, stronger, higher-modulus metals such as copper and aluminum. Useful compromises between these sets of opposed properties are effected by alloying to produce polyphase structures with intermediate properties, and by employing layered constructions in which softer and weaker surface layers are reinforced by one or more harder, stronger backing layers.

Bearing Material Microstructures. All commercially significant bearing metals, with the exception of silver, are polyphase alloys. As indicated below, these polyphase alloys can be classified according to basic microstructural types.

Type 1: Soft Matrix with Discrete Hard Particles (Fig. 3). Lead and tin babbitts are of this type. The compatibility, conformability, and embeddability of these alloys are somewhat lower than those of unalloyed lead or tin due to the presence of hard intermetallic and metalloid particles, which effectively increase bulk strength properties.

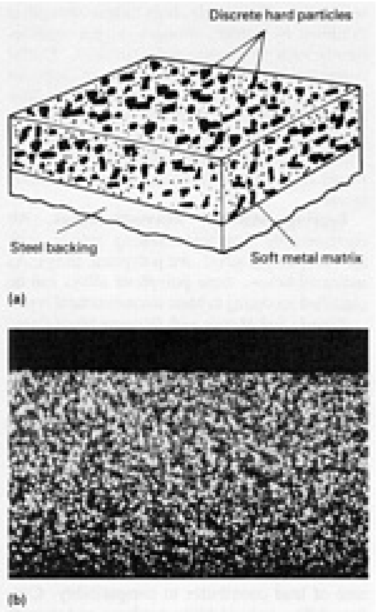

Fig. 3 Type I microstructure present in lead and tin babbitt bearing alloys. (a) Schematic showing discrete hard particles dispersed in a soft matrix that is bonded to a steel backing. (b) Photomicrograph of a lead-base babbitt in which lead is present in the dark phase and antimony in the light phase. 50×

Type II: Interlocked Soft and Hard Continuous Phases (Fig. 4). Many copper-lead and leaded bronze alloys are of this type. These structures consist of continuous mutually supporting copper and lead sponges. A large volume of lead contributes to compatibility. Conformability, embeddability, hardness, and strength properties are intermediate between those of lead and those of copper.

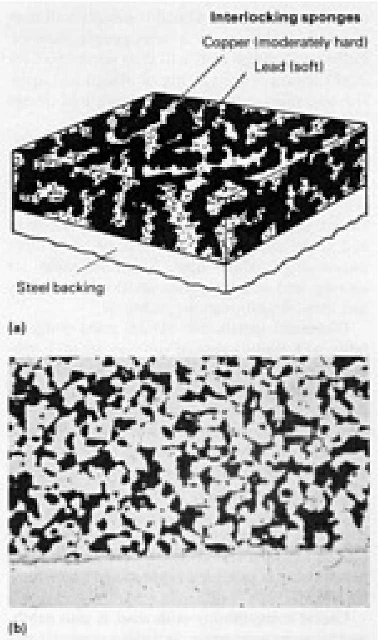

Fig. 4 Type II microstructure present in numerous copper-lead and leaded bronze bearing alloys. (a) Schematic showing interlocking soft-phase (lead) constituent and hard-phase (copper) constituent in a spongelike

structure that is bonded to a steel backing. (b) Photomicrograph of a copper-lead babbitt in which lead is present in the dark phase and copper is present in the light phase. 50×

Type III: Strong Matrix with Discrete Soft-Phase Pockets (Fig. 5). Low-lead bronzes and some aluminum-tin alloys are of this type. These structures consist of a continuous copper-base or aluminum-base metallic matrix that contains discrete pools or pockets of lead or tin. Conformability, embeddability, strength, and hardness properties are dictated by the strength of the matrix phase. Compatibility is enhanced by the soft metal phase that is exposed at the bearing surface.

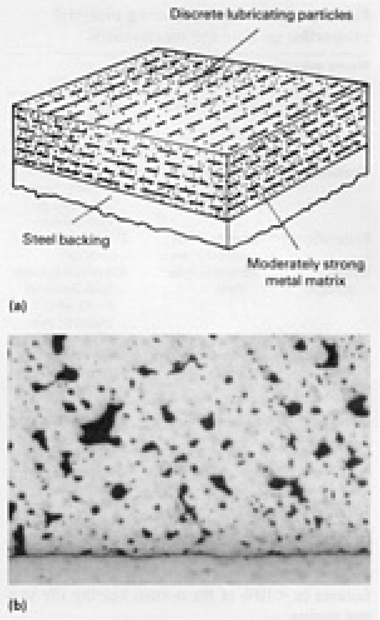

Fig. 5 Type III microstructure commonly found in low-lead bronzes and some aluminum-tin bearing alloys. (a) Schematic showing discrete soft particles dispersed in a hard matrix that is bonded to a steel backing. (b) Photomicrograph of a medium-lead tin bronze in which lead is present in the dark phase and copper-tin is present in the light phase. 50×

Mixed microstructures that combine the characteristics of types I and III are exhibited by aluminum-silicon-tin alloys and aluminum-silicon-lead alloys. In these alloys, the aluminum matrix contains both dispersed hard particles (silicon) and soft-phase (lead or tin) particles.

One of the most useful concepts in bearing material design came in 1941 with the recognition that the effective load capacities and fatigue strengths of lead and tin alloys are sharply increased when these alloys are used as thin layers intimately bonded to strong bearing backs of bronze or steel. Use is made of this principle (Fig. 6) in two-layer constructions (Fig. 7) using a surface layer of lead or tin alloy, usually no more than 0.13 mm (0.005 in.) thick. Unimpaired compatibility is provided by such a layer, together with reasonably high levels of conformability and embeddability. Other useful compromises can be effected between surface and bulk properties by employing an intermediate copper or aluminum alloy layer between the surface alloy layer and a steel back (Fig. 8). In these three-layer constructions, use of a surface layer thickness as low as 0.013 mm (0.0005 in.) offers even more favorable compromises between surface and bulk properties than are possible with two-layer constructions.

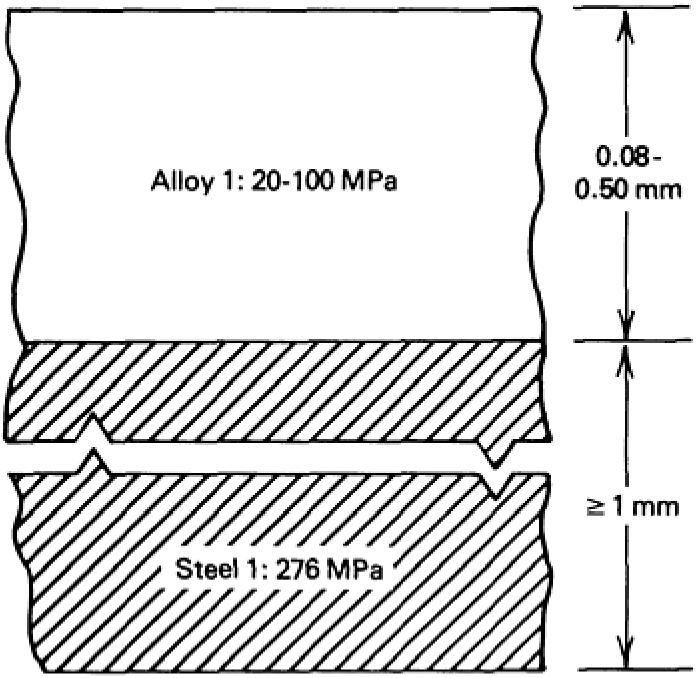

Fig. 7 Compressive yield strength levels typically obtained in the individual layers of a bilayer construction bearing material

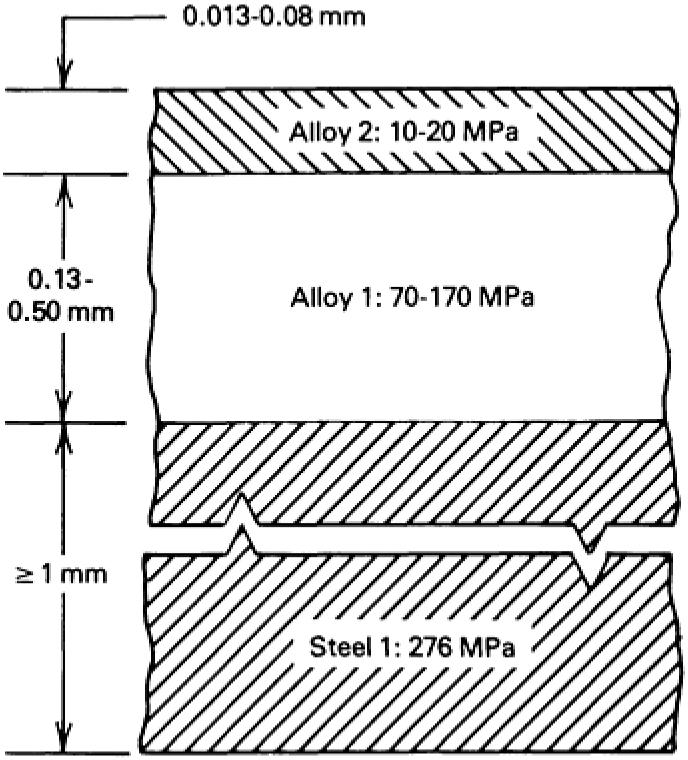

Fig. 8 Compressive yield strength levels typically obtained in the individual layers of a trilayer construction bearing material

Corrosion Resistance. Bearing failure due to corrosion alone is rare. Corrosion usually interacts with mechanical and thermal factors to produce failure by fatigue or seizure under conditions the bearing normally would be able to tolerate. To a considerable extent, bearing corrosion can be avoided by use of oxidation inhibitors in commercial lubrication oils, and by periodic oil changes. There are, however, many situations in which neither of these practices is dependable and where bearing materials with inherently high corrosion resistance should be used.

Commercially pure lead is susceptible to corrosion by fatty acids. Lead-base and copper-lead bearing alloys can suffer severe corrosion damage in acidic lubricating oils. Tin additions in excess of ~5% provide effective protection against this kind of corrosion, and for this reason tin is used extensively in lead-base bearing alloys. Both copper and lead are attacked by acidic oils that contain sulfur. This is of particular concern with copper-lead and leaded bronze bearing alloys. Effective protection can be obtained by employing layered construction, with a surface layer of either a lead alloy containing tin or a tin alloy. As long as the corrosion-resistant surface layer is intact, the underlying copper-lead alloy will not suffer damage by corrosion.

Tin and aluminum bearing alloys are substantially impervious to corrosion by the products of oil oxidation, and they are used extensively in applications where the potential for lubricating oil corrosion is known to be high. Although lubricating oil oxidation and contamination are the most common causes of bearing damage by corrosion, other sources of bearing corrosion, such as seawater, animal and vegetable oils, and corrosive gas, should be recognized. Selection and specification of a bearing material for a specific application should take into account the anticipated service conditions under which the bearings will have to operate, and the potential for corrosion that these conditions may stimulate.

Heat and Temperature Effects. The reduced mechanical strength of bearing liner materials at elevated temperatures is an important consideration in the selection of a bearing material for a given application. Fatigue strength, compressive yield strength, and hardness decrease significantly with increased bearing operating temperature. As shown by the softening curves in Fig. 9, lead-base and tin-base bearing alloys are most severely limited in this respect, and copper alloys the least.

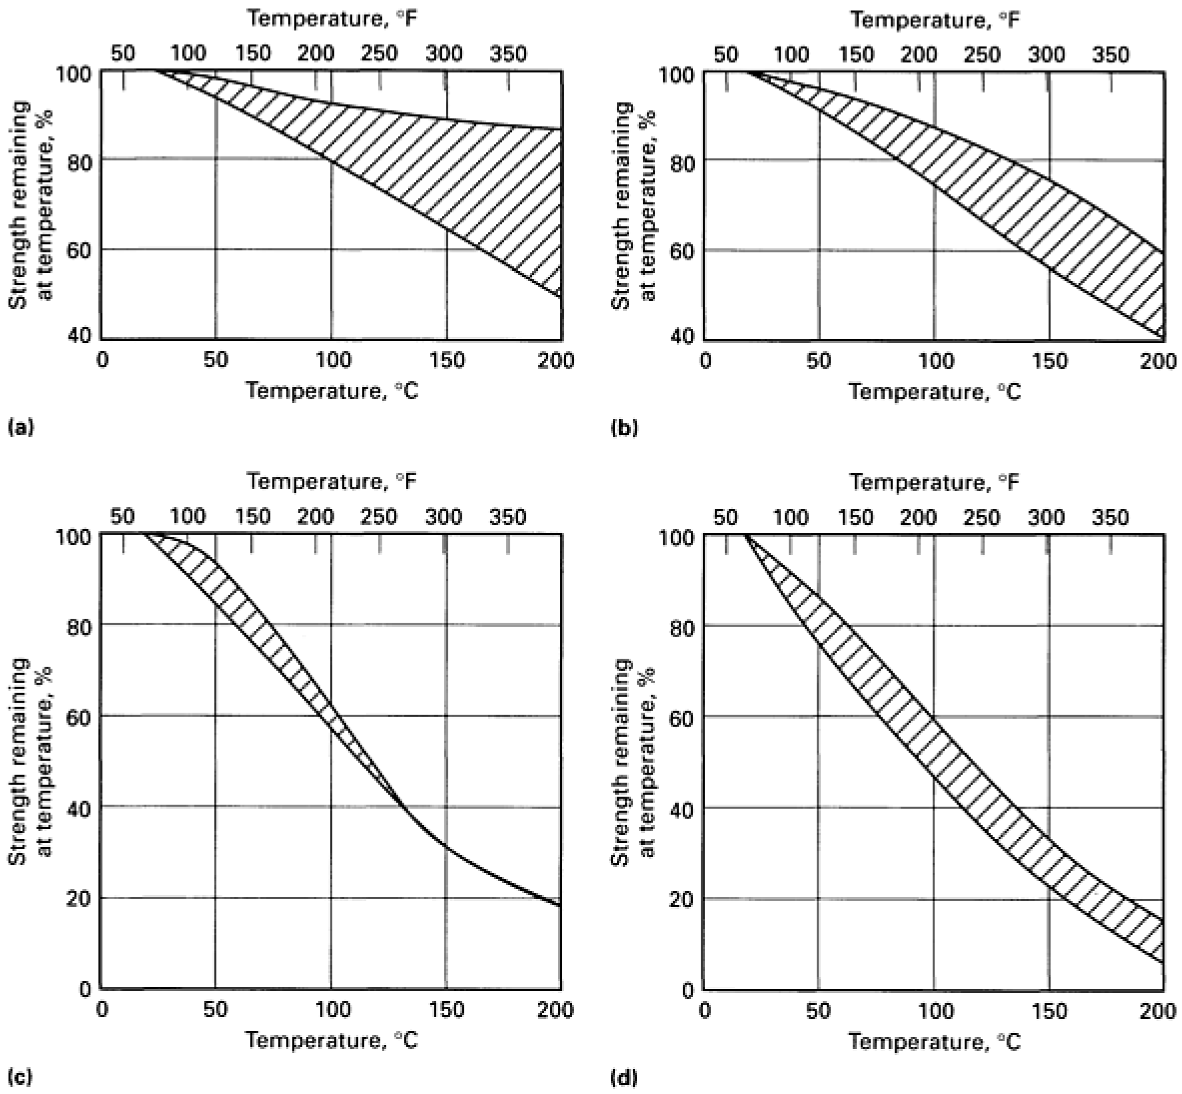

Fig. 9 Strength retention at elevated temperatures for selected bearing alloys. (a) Copper-base alloys. (b) Aluminum-base alloys. (c) Zinc-base alloys. (d) Lead-base alloys and tin-base alloys

Load Capacity. The load capacity of a bearing material is defined as the maximum unit pressure under which the material can operate without excessive friction or wear damage. Load capacity ratings published as guides for machinery designers generally represent upper limits, which may be safely employed only under very good conditions of lubricant film integrity, counterface finish, mechanical alignment, and temperature control.

In cyclic-load service (for example, in crankshaft bearings), load capacity is primarily limited by fatigue strength. In steady-load service, it depends more strongly on compressive yield strength, reflected in indentation hardness. In all cases, the strength of the material at operating temperature will be the determining factor that governs the choice of bearing material. Temperature and its control are therefore critically important to the successful operation of sliding bearings.

Although useful to the designer as reference values, load capacity ratings must be recognized as imprecise and somewhat judgmental approximations. They are not guaranteed or directly measurable material properties.

Bearing Material Systems

Because of the widely varying conditions under which bearings must operate, commercial bearing materials have evolved as specialized engineering materials systems rather than as commodity products. They are used in relatively small tonnages and are produced by a relatively small number of manufacturers. Much proprietary technology is involved in

alloy formulation and processing methods. Successful selection of a bearing material for a specific application often requires close technical cooperation between the user and the bearing producer.

Single-Metal Systems

Most single-metal sliding bearing are made from either copper alloys or aluminum alloys. Some use is also made of cast zinc-base alloys which serve as lower-cost substitutes for solid bronze. Commercially significant alloys that are used as single-metal bearings are listed in Table 2.

Table 2 Single-metal bearing material systems

Class	Material	Bearing performance characteristics[(a)]					Load capacity rating[(c)]		Typical applications
		Compatibility	**Conformability**	**Embeddability**	**Fatigue strength**	**Corrosion resistance[(b)]**	**MPa**	**ksi**	
1	Commercial bronze (10% Zn)	F	E	F	D	B	28	4	Bushings, washers
2	Tin bronze High lead (16-25% Pb)	D	D	D	D	E	21	3	Mill-machinery bearings, pump bearings, railroad-car bearings
	Medium lead (4-10% Pb)	E	E	E	C	D	28	4	Wrist pin bushings, pump bushings, electric-motor bushings, track-roller bushings, farm-equipment gear bushings, mill-machinery bearings, machine-tool bearings
	Low lead (1-4% Pb)	F	F	F	B	B	34	5	Wrist pin bushings, mill-machinery bearings, machine-tool bearings, earth-moving machinery bearings, farm-equipment gear bushings
	Unleaded	F	F	F	A	B	34	5	Wrist pin bushings, mill-machinery bearings, machine-tool bearings, railroad-car wheel bearings
3	Aluminum alloy, low tin	D	D	D	D	A	28	4	Connecting-rod main bearings, bushings, mill-machinery bearings
4	Zinc alloy 12% Al	E	E	F	B	E	28	4	Compressor bearings, pump bushings, mill-machinery bearings, earth-moving machinery bearings
	27% Al	E	F	F	A	E	34	5	Compressor bearings, pump bushings, mill-machinery bearings, earth-moving machinery bearings
5	Porous metal Bronze	C	C	C	D	B	14	2	Electric motor bushings, home appliance bearings, agricultural equipment bushings
	Iron	D	D	C	D	B	21	3	Electric motor bushings, home appliance bearings, agricultural equipment bushings
	Iron-bronze	D	D	C	D	B	21	3	Electric motor bushings, home appliance bearings, agricultural equipment bushings

(a) Bearing performance characteristics rated on scale A through F, where A is highest (best) and F is lowest (poorest).

(b) Corrosion resistance refers to corrosion by fatty acids of the kind that can form in petroleum-base oils.

(c) Load capacity rating approximates maximum safe unit loading for operation with steel journal under cyclic loading and excellent lubrication.

Wide ranges of compositions and properties are available in the older copper group. Brasses and bronzes have been widely used in bearing applications since the mid-1800s. Interest in the use of aluminum alloys was stimulated by World War II metal shortages and greatly accelerated by the commercial introduction of aluminum-tin bearing alloys in 1946. Since then, metal economics have dictated the use of aluminum alloy bearings, but brasses and bronzes continue to be preferred by many designers of heavy and special-purpose machinery.

Single-metal systems do not exhibit outstandingly good surface properties, and their tolerance of boundary and thin-film lubrication conditions is limited. As a result, the load capacity rating for a single-metal bearing usually is low relative to the fatigue strength of the material from which it was made. Because of their metallurgical simplicity, these materials are well suited for small-lot manufacturing from cast tubes or bars, using conventional machine shop processes.

Copper Alloys. Except for commercial bronze and low-lead tin bronze, copper alloys in single-metal systems are almost always used in cast form. This provides thick bearing walls (≥3.20 mm, or 0.125 in.) that are strong enough so that the bearing is retained in place when press fitted into the housing.

Commercial bronze and medium-lead tin bronze alloys C83420 and C83520 are used extensively in the form of wrought strip for thin-wall bushings, which are made in large volumes by high-speed press forming. The relatively poor compatibility of these alloys can be improved by embedding a graphite-resin paste in rolled or pressed-in indentations, so that the running surface of the bushing consists of interspersed areas of graphite and bronze. Such bushings are widely used in automotive engine starting motors.

The lead in leaded tin bronzes is present in the form of free lead that is dispersed throughout a copper-tin matrix so that the bearing surface consists of interspersed areas of lead and bronze. In general, the best selection of materials from this group for a given application will be the highest-lead composition that can be used without risking excessive wear, plastic deformation, or fatigue damage.

Aluminum Alloys. Virtually all solid aluminum bearings used in the United States are made from alloys containing from 5.5 to 7% Sn, plus smaller amounts of copper, nickel, silicon, and magnesium. Starting forms for bearing fabrication include cast tubes as well as rolled plate and strip, which can be press formed into half-round shapes. As is the case with solid bronze bearings, relatively thick bearing walls are employed in solid aluminum alloy bearings.

The tin in these alloys is present in the form of free tin that is dispersed throughout an aluminum matrix so that the bearing surfaces consist of interspersed areas of aluminum and tin. Surface properties are enhanced by the free tin in much the same way that those of bronze are improved by the presence of free lead.

The high thermal expansion of aluminum poses special problems in maintaining press fit and running clearances. Various methods are employed for increasing yield strength (for example, heat treatment and cold work) to overcome plastic flow and permanent deformation under service temperatures and loads.

Zinc Alloys. During the past 20 years, zinc-aluminum-copper casting alloys have been used to replace cast bronze alloys in certain low-speed machinery bearing applications. This practice has advanced farthest in Europe, as an outgrowth of World War II material substitution efforts.

These alloys do not contain any soft microconstituents that correspond to the lead used in bearing bronzes and to the tin in cast aluminum bearing alloys. To a considerable degree, compatibility of the zinc-base alloys seems to derive from their chemical behavior with hydrocarbon lubricants. Formation of a stable low shear strength film of zinc-base soap appears to be an important factor.

Porous Metal Bushings. Oil-impregnated porous metal bushings can also be included in the single-metal systems category. The materials used for these bushings include unleaded and leaded tin-bronze, bronze-graphite, iron-carbon, iron-copper, and iron-bronze-graphite compositions. Oil content of these materials constitutes 8 to 30% of total volume.

Bimetal Systems

All bimetal systems employ a strong bearing back to which a softer, weaker, relatively thin layer of a bearing alloy is metallurgically bonded. Low-carbon steel is by far the most widely used bearing-back material, although alloy steels, bronzes, brasses, and (to a limited extent) aluminum alloys are also used. The bimetal bearing material systems currently in significant commercial use are classified in Table 3.

Table 3 Bimetal bearing material systems

Class	Backing layer	Surface layer	Bearing performance characteristics[a]					Load capacity rating[c]		Typical applications
			Compatibility	**Conformability**	**Embeddability**	**Fatigue strength**	**Corrosion resistance[b]**	**MPa**	**ksi**	
1	Steel	Tin babbitt:								
		0.25-0.50 mm (0.010-0.020 in.)	A	A	A	F	A	14	2	Connecting-rod and main bearings, camshaft bearings, electric-motor bushings, pump bushings, thrust washers
		0.102 mm (0.004 in.)	A	B	B	E	A	17	2.5	
2	Steel	Lead babbitt:								
		0.25-0.50 mm (0.010-0.020 in.)	A	A	A	F	B	14	2	Connecting-rod and main bearings, camshaft bearings, transmission bushings, pump bushings, thrust washers
		0.102 mm (0.004 in.)	A	B	B	E	B	17	2.5	
3	Steel	Aluminum alloy:								
		High tin	B	C	C	D	A	41	6	Connecting-rod and main bearings, camshaft bearings, transmission bushings, pump bushings, thrust washers
		Medium-tin	B	C	C	C	A	55	8	Connecting-rod and main bearings, camshaft bearings, transmission bushings, pump bushings, thrust washers
		High-lead	B	C	C	C	A	55	8	Connecting-rod and main bearings, camshaft bearings, transmission bushings, pump bushings, trust washers
		Low-tin	D	D	D	C	A	55	8	Camshaft bearings, transmission bushings, thrust washers
		Tin-free	D	D	D	C	A	55	8	Camshaft bearings, transmission bushings, thrust washers
4	Steel	Copper alloy:								
		Copper-lead	C	C	C	C	F	38	5.5	Connecting-rod and main bearings, camshaft bearings
		High-lead bronze	D	D	D	C	E	45	6.5	Camshaft bearings, turbine bearings, pump bushings, thrust washers
		Medium-lead bronze	E	E	E	B	D	55	8	Piston pin bushings, rocker-arm bushings, wear plates, steering-knuckle bushings, guide bushings, thrust washers
5	Medium-lead bronze	Tin babbitt, 0.25-0.50 mm (0.010-0.020 in.)	A	A	A	F	B	14	2	Connecting-rod and main bearings, thrust washers, railroad-car journal bearings, mill-machinery bearings
6	Medium-lead bronze	Lead babbitt: 0.25-0.50 mm (0.010-0.020 in.)	A	A	A	F	C	14	2	Connecting-rod and main bearings

7	Medium-lead-bronze	Lead babbitt: mm (0.001 in.)	0.025	A	C	B	C	C	48	7	Connecting-rod and main bearings
8	Aluminum alloy, low tin	Lead babbitt, mm (0.001 in.)	0.025	A	C	B	D	C	41	6	Connecting-rod and main bearings

(a) Bearing performance characteristics rated on scale A through F, where A is highest (best) and F is lowest (poorest).

(b) Corrosion resistance refers to corrosion by fatty acids of the kind that can form in petroleum-base oils.

(c) Load capacity rating approximates maximum safe unit loading for operation with steel journal under cyclic loading and excellent lubrication.

The strengthening effect of a steel bearing back is illustrated clearly for classes 3 and 4 in Table 3; these ratings can be compared with those for the aluminum and copper alloy single-metal systems in Table 2. When steel bearing backs are employed, load-capacity ratings for both copper and aluminum alloys are sharply increased above those of the corresponding single metals without degrading any other properties. Similarly, in classes 1, 2, 5, 6, and 7, the strong bearing-back materials permit use of lead and tin alloys that have extremely good surface properties but that are so low in strength that they can be used as single-metal bodies only under very light loads.

The strengthening effect of thin-layer construction on lead and tin alloys is illustrated in Table 3 (classes 1 and 2), where a 50% increase in load capacity is achieved by reducing babbitt layer thickness. Although similar behavior has been observed with aluminum and copper alloys, the thin-liner effects are less dramatic. Liner thicknesses employed with these stronger alloys are established by metal economics and manufacturing process considerations, rather than by strength/thickness relationships.

Deterioration in surface properties with increasing liner alloy fatigue strength is clearly seen by the comparison of classes 1 and 2 with classes 3 and 4, and by comparisons within classes 3 and 4 (Table 3). In practice, only those systems with surface properties rated "D" or better are successful under boundary and thin-film lubrication conditions. This restricts the use of bimetal materials in connecting-rod and main bearings to loads of $\leq$55 MPa ($\leq$8 ksi).

Bronze-back bearings (see Table 3, classes 5, 6, and 7) do not exhibit combinations of performance characteristics substantially different from those of steel-back bearings. The practical advantages of bronze as a bearing-back material lie partly in the economics of small-lot manufacturing and partly in the relative ease with which worn bronze-back bearings can be salvaged by rebabbitting and remachining. From the standpoint of performance, the advantage of bronze over steel as a bearing-back material is the protection bronze affords against catastrophic bearing seizure in case of severe liner wear or fatigue. Similar protection is provided by the aluminum alloy bearing back in class 8.

Although the surface properties of bronze bearing-back materials are not impressive, they are superior to those of steel, and these "reserve" bearing properties can be of considerable practical importance in large expensive machinery used in certain critical applications.

Trimetal Systems

Virtually all trimetal systems employ a steel bearing back, an intermediate layer of relatively high strength, and a tin alloy or lead alloy surface layer. The systems in current commercial use are listed by classes in Table 4. Most of these systems are derived from the bimetal systems of Table 3 (classes 3 and 4) by the addition of a lead-base or tin-base surface layer.

Table 4 Trimetal bearing material systems

Class	Backing layer	Intermediate layer	Bearing performance characteristics[(a)]						Load capacity rating[(c)]		Typical applications
			Surface layer	**Compatibility**	**Conformability**	**Embeddability**	**Fatigue strength**	**Corrosion resistance[(b)]**	**MPa**	**ksi**	
1	Steel	Medium-lead bronze	Tin babbitt, 0.25-0.50 mm (0.010-0.020 in.)	A	A	A	F	B	14	2	Large connecting-rod and main bearings, bushings
2	Steel	High-lead bronze	Tin babbitt, 0.25-0.50 mm (0.010-0.020 in.)	A	A	A	F	B	14	2	Large connecting-rod and main bearings, bushings
3	Steel	Copper-lead	Lead babbitt, 0.075 mm (0.003 in.)	A	B	B	E	C	21	3	Connecting-rod and main bearings, camshaft bearings
4	Steel	Copper-lead	Lead babbitt, 0.025 mm (0.001 in.)	A	C	C	B	C	59	8.5	Connecting-rod and main bearings, bushings
5	Steel	High-lead bronze	Lead babbitt, 0.025 mm (0.001 in.)	A	C	C	B	C	83	12	Connecting-rod and main bearings, thrust washers
6	Steel	Medium-lead bronze	Lead babbitt, 0.025 mm (0.001 in.)	A	D	D	A	C	83	12	Connecting-rod and main bearings
7	Steel	Aluminum, low tin	Lead babbitt, 0.025 mm (0.001 in.)	A	C	C	B	B	55	8	Connecting-rod and main bearings
8	Steel	Aluminum, tin free, low alloy	Lead babbitt, 0.025 mm (0.001 in.)	A	C	C	B	B	55	8	Connecting-rod and main bearings
9	Steel	Aluminum, tin free, low alloy, precipitation hardened	Lead babbitt, 0.025 mm (0.001 in.)	A	C	C	B	B	76	11	Connecting-rod and main bearings
10	Steel	Aluminum, tin free, high alloy	Lead babbitt, 0.025 mm (0.001 in.)	A	C	C	B	B	76	11	Connecting-rod and main bearings
11	Steel	Silver	Lead babbitt, 0.025 mm (0.001 in.)	A	D	D	A	B	83	12	Connecting-rod and main bearings for aircraft reciprocating engines

(a) Bearing performance characteristics rated on scale A through F, where A is highest (best) and F is lowest (poorest).

(b) Corrosion resistance refers to corrosion by fatty acids of the kind that can form in petroleum-base oils.

(c) Load capacity rating approximates maximum safe unit loading for operation with steel journal under cyclic loading and excellent lubrication.

The strengthening effects of thin-layer construction are notable in those systems that incorporate electroplated lead alloy surface layers ≤0.025 mm (≤0.001 in.) thick (Table 4, classes 4 through 11). Comparison of fatigue strength and load capacity ratings of these systems with those of the corresponding bimetal systems in Table 3 shows that the thin lead alloy surface layer upgrades not only surface properties but also fatigue strength. The increase in fatigue strength can be attributed at least in part to the elimination of stress raisers, from which fatigue cracks can propagate.

Class 1 and class 2 trimetal systems comprise leaded bronze intermediate layers with relatively thick tin alloy surface layers. These represent an evolution from bronze-back babbitt construction wherein steel has replaced most of the bronze. This produces the expected economy and bearing-back yield strength, but retains the desirable "reserve" bearing properties exhibited by bronze-back construction.

Class 11 trimetal systems, which have silver intermediate layers, are too costly for most commercial applications. However, they provide an unequaled combination of high load capacity and corrosion resistance. They continue to have limited use in radial piston engines for aircraft.

Trimetal systems with electroplated lead-base surface layers and copper or aluminum alloy intermediate layers provide the best available combinations of cost, fatigue strength, and surface properties. Such bearings have high tolerances for boundary and thin-film lubrication conditions, and thus can be used under higher loads than can any of the bimetal systems. Although more costly than the corresponding steel-back bimetal systems, they are used in some high-volume automotive applications as well as in larger mobile and stationary engines. A highly developed body of mechanical, metallurgical, and chemical manufacturing technology has been established in the plain bearing industry, and this technology permits mass production of precision trimetal bearings without a severe cost penalty.

Bearing Alloys

Sliding bearing alloys can be grouped as follows:

- Tin-base alloys
- Lead-base alloys
- Copper-base alloys
- Aluminum-base alloys
- Silver-base alloys
- Zinc-base alloys
- Additional metallic materials (gray cast irons and cemented carbides)
- Nonmetallic materials (nylon, PTFE, carbon-graphite, wood, rubber, and laminated phenolics)

Tin-Base Alloys

Tin-base bearing materials (babbitts) are alloys of tin, antimony, and copper that contain limited amounts of zinc, aluminum, arsenic, bismuth, and iron. The compositions of tin-base bearing alloys, according to ASTM B 23, SAE, and ISO specifications, are shown in Table 5.

Table 5 Designations and nominal composition of tin-base bearing alloys

Designation[(a)]				Composition, %				Product form	Applications
UNS	**SAE**	**ISO**	**ASTM (B 23)**	**Sn**	**Sb**	**Cu**	**Other**

(a) UNS, unified numbering system; SAE, Society of Automotive Engineers; ISO, International Organization for Standardization; ASTM, American Society for Testing and Materials

The presence of zinc in these bearing metals generally is not favored. Arsenic increases resistance to deformation at all temperatures; zinc has a similar effect at 38 °C (100 °F) but causes little or no change at room temperature. Zinc has a marked effect on the microstructures of some of these alloys. Small quantities of aluminum (even <1%) will modify their microstructures. Bismuth is objectionable because, in combination with tin, it forms a eutectic that melts at 137 °C (279 °F). At temperatures above this eutectic, alloy strength is decreased appreciably.

Bulk mechanical properties of ASTM grades 1 to 3 are shown in Table 6. These properties have some value for initial materials screening comparisons of alloys; but they are not reliable predictors of the performance of thin layers bonded to a strong backing, which is the manner in which tin-base babbitts are usually used in modern bearing practice. Layer thickness effects (Fig. 5) and temperature effects (Fig. 7) are more important practical considerations than the mechanical property differences among the various alloy compositions.

(b) Values are for die-cast alloy specimens.

Compared with most other bearing materials, tin alloys have low resistance to fatigue, but their strength is sufficient to warrant their use under low-load conditions. These alloys are commercially easy to bond and handle and they have excellent antiseizure qualities. Their excellent corrosion-resistant properties make these alloys especially well-suited for bearing applications in compressors, electric motors, and food-processing equipment.

Tin-base alloys vary in microstructure in accordance with their composition. Alloys that contain about 0.5 to 8% Cu and <8% Sb are characterized by a solid-solution matrix in which needles of a copper-rich constituent and fine rounded particles of precipitated SbSn are distributed. The proportion of the copper-rich constituent increases with copper content. SAE 12 (ASTM grade 2) has a structure of this type in which the needles often assume a characteristic hexagonal starlike pattern. Alloys that contain ~0.5 to 8% Cu and >8% Sb exhibit primary cuboids of SbSn, in addition to needles of the copper-rich constituent in the solid-solution matrix. In alloys with ~8% Sb and ~5 to 8% Cu, rapid cooling suppresses formation of the SbSn cuboids. This is particularly true of alloys containing lower percentages of copper.

Lead-Base Alloys

Lead-base bearing materials (lead babbitts) are alloys of lead, tin, antimony, and in many cases, arsenic. Many such alloys have been used for centuries as type metals, and were probably first employed as bearing materials because of the properties they were known to possess. The advantage of arsenic additions have been generally recognized since 1938.

Nominal compositions of the most widely used lead babbitts according to ASTM, SAE, and ISO specifications are listed in Table 7. Additional information on mechanical properties of some of these alloys is given in Table 8.

Table 7 Designations and nominal composition of lead-base bearing alloys

Comments made in the section "Tin-Base Alloys" in this article concerning the significance of bulk mechanical properties of tin-base babbitt alloys apply equally to those of lead-base alloys.

For many years, lead-base bearing alloys were considered to be only low-cost substitutes for tin alloys. However, the two groups of alloys do not differ greatly in antiseizure characteristics, and when lead-base alloys are used with steel backs and in thicknesses <0.75 mm (<0.03 in.), they have fatigue resistance that is equal to, if not better than, that of tin alloys. Bearings of any of these alloys remain serviceable longest when they are ≤0.13 mm (≤0.005 in.) thick (See Fig. 5).

In the absence of arsenic, the microstructures of these alloys comprise cuboid primary crystals of SbSn or of antimony embedded in a ternary mixture of Pb-Sb-SbSn in which lead forms the matrix. The number of these cuboids per unit volume of alloy increases as antimony content increases. If antimony content is >15%, the total amount of the hard constituents increases to such an extent that the alloys become too brittle to be useful as bearing materials.

Arsenic is added to lead babbitts to improve their mechanical properties, particularly at elevated temperatures. All lead babbitts are subject to softening or loss of strength during prolonged exposure to the temperatures (95 to 150 °C, or 200 to 300 °F) at which they serve as bearings in internal combustion engines. Addition of arsenic minimizes such softening. Under suitable casting conditions (see the section "Casting Processes" in this article), the arsenical lead babbitts (for example, SAE 15 [ASTM grade 15]) develop remarkably fine and uniform structures. They also have better fatigue strength than arsenic-free alloys.

Pouring temperature and rate of cooling markedly influence the microstructures and properties of lead alloys, particularly when they are used in the form of heavy liners for railway journals. High pouring temperatures and low cooling rates, which typically result from the use of overly hot mandrels, promote segregation and formation of a coarse structure. A coarse structure may cause brittleness, low compressive strength, and low hardness. Therefore, low pouring temperatures (325 to 345 °C, or 620 to 650 °F) usually are recommended. Because these alloys remain relatively fluid almost to the point of complete solidification (~240 °C, or 465 °F, for most compositions), they are easy to manipulate and can be handled with no great loss of metal from drossing.

Lead-Base Electroplated Overlays. The improvement in fatigue life that can be achieved by decreasing babbitt layer thickness has already been noted. Economically as well as mechanically, it is difficult to consistently achieve very thin uniform babbitt layers bonded to bimetal shells by casting techniques. Therefore, the process of electroplating (see the section "Electroplating Processes" in this article) a thin precision babbitt layer on a very accurately machined bimetal shell was perfected. Specially designed plating racks allow the thickness of the plated babbitt layer to be regulated so accurately that further machining is usually not required.

Electroplated tin alloys were found to be generally inferior to lead alloys, and only lead alloys are in commercial use as electroplated bearing overlays. Table 9 lists the four most commonly used compositions. SAE alloy 192 is the most frequently used. Tin in alloys 191, 192, and 193 and indium in alloy 194 impart corrosion resistance. Tin also increases wear resistance. Both copper and indium enhance fatigue resistance.

Table 9 Designations and nominal composition of lead-base electroplated overlay alloys

Designation		Composition, %			
SAE	**ISO**	**Pb**	**Sn**	**Cu**	**In**
Alloy 191	PbSn10	90	10	. . .	. . .
Alloy 192	PbSn10Cu2	88	10	2	. . .
Alloy 193	. . .	80	18	2	. . .
Alloy 194	PbIn7	93	. . .	. . .	7

When a tin-containing overlay is plated directly onto a copper-lead or bronze surface, the tin has a tendency to migrate to the copper interface, forming a brittle copper-tin intermetallic compound. This decreases the corrosion resistance of the overlay and causes embrittlement along the bond line. To avoid this deterioration, a thin continuous barrier layer, preferably nickel ~1.3 μm (~52 μin.) thick, is plated onto the copper alloy surface just prior to plating of the overlay. In addition to providing better surface behavior, overlays improve fatigue performance of some intermediate layers by preventing cracking in this layer. Plated overlays generally range in thickness from 0.013 to 0.05 mm (0.0005 to 0.002 in.), with fatigue life increasing markedly as overlay thickness decreases. In order to take full advantage of the improved fatigue life achieved with thin overlays, it is necessary to minimize assembly imperfections (such as misalignment) and to maintain close tolerances on machined shafts and bearing bores. Engine components must be thoroughly cleaned before assembly, and adequate air and lubricant filtration must be maintained if the overlay is to survive during the useful life of the bearing. Under adverse wear conditions, however, premature removal of the overlay will not necessarily impair operation of the bearing, because the exposed intermediate bearing alloy layer should continue to function satisfactorily.

Copper-Base Alloys

Copper-base bearing alloys comprise a large family of materials with a wide range of properties. They include commercial bronze, copper-lead alloys, and leaded and unleaded tin bronzes. They are used alone in single-metal bearings, as bearing backs with babbitt surface layers, as bimetal layers bonded to steel backs, and as intermediate layers in steel-backed trimetal bearings (see Tables 2, 3, and 4).

The moderate strength and hardness of pure copper are readily increased by alloying, most commonly with tin (with which copper forms a solid solution). Lead is present in cast copper-base bearing alloys as a nearly pure, discrete phase, because its solid solubility in the matrix is practically nil. The lead phase, which is exposed on the running surface of a bearing, constitutes a site vulnerable to corrosive attack under certain operating conditions.

The antifriction behavior of copper-base bearing alloys improves as lead content increases, although at the same time strength is degraded because of increased interruption of the continuity of the copper alloy matrix by the soft weak lead. Thus, through judicious control of tin content, lead content, and microstructure, a large family of bearing alloys has evolved to suit a wide variety of bearing applications.

Table 10 gives specification numbers and nominal compositions of copper-base bearing alloys, as well as the forms in which the alloys are used and general notations on typical product applications. The information in Table 10 should be used in conjunction with the appropriate portions of Tables 2, 3, and 4 and with the brief descriptions that follow.

Commercial Bronze. Lead-free copper alloys are characterized by poor antifriction properties but fairly good load-carrying ability. Wrought commercial bronze strip (SAE 795) with 10% Zn can be readily press formed into cylindrical bushings and thrust washers. Strength can be increased by cold working this inexpensive material.

Unleaded Tin Bronze. The unleaded copper-tin alloys are known as phosphor bronzes because they are deoxidized with phosphorus. They are used principally in cast form as shapes for specific applications, or as rods or tubes from which solid bearings are machined. They have excellent strength and wear resistance, both of which improve with increasing tin content, but poor surface properties. They are used for bridge turntables and trunnions in contact with high-strength steel, and in other slow-moving applications.

Low-Lead Tin Bronzes. The inherently poor machinability of tin bronzes can be improved by adding small amounts of lead. Such additions do not significantly improve surface properties, however, and applications for these alloys are essentially the same as those for unleaded tin bronzes.

Medium-Lead Tin Bronzes. The only wrought strip material in this group of alloys is SAE 791, which is press formed into solid bushings and thrust washers. C83600 is used in cast form as bearing backs in bimetal bearings. SAE 793 is a low-tin, medium-lead alloy that is cast or sintered on a steel back and used as a surface layer for medium-load bimetal bushings. SAE 792 is higher in tin and slightly higher in lead; it is cast or sintered on a steel back and used for heavy-duty applications such as wrist pin bushings and heavy-duty thrust surfaces.

High-Lead Tin Bronzes. These contain medium-to-high amounts of tin, and relatively high lead contents to markedly improve antifriction characteristics. SAE 794, widely used in bushings for rotating loads, has the same bronze matrix composition as SAE 793 (4.5% Sn) but three times as much free lead. It is cast or sintered on a steel back and used for somewhat higher speeds and lower loads than alloy 793. The bronze matrix of SAE 794 is much stronger than that of a plain 75-25 copper-lead alloy. Alloy 794 can be used as the intermediate layer with a plated overlay in heavy-duty trimetal bearing applications such as main and connecting-rod bearings in diesel truck engines. This construction provides the highest load-carrying ability available in copper alloy trimetal bearings.

Copper-Lead Alloys. These are used extensively in automotive, aircraft, and general engineering applications. These alloys are cast or sintered to a steel backing strip from which parts are blanked and formed into full-round or half-round shapes depending on final application. Copper-lead alloys continuously cast on steel strip typically consist of copper dendrites perpendicular and securely anchored to the steel back, with an interdendritic lead phase. In contrast, sintered copper-lead alloys of similar composition are composed of more equiaxed copper grains with an intergranular lead phase.

High-lead alloy SAE 48 can be used bare on steel or cast iron journals. Tin content in this alloy is restricted to a minimum value to maintain a soft copper matrix, which together with the high lead content improves the antifriction/antiseizure properties of the alloy. Bare bimetal copper-lead bearings are used infrequently today because the lead phase, present as nearly pure lead, is susceptible to attack by corrosive products that can form in the crankcase lubricant during extended oil-change periods. Therefore, most copper-base alloys with lead contents >20%, including both SAE alloy 48 and alloy 49, are now used with plated overlays in trimetal bearings for automotive and diesel engines.

SAE 485 is a special sintered and infiltrated composite material, produced by methods described in the section "Powder Metallurgy Processes" in this article. By these methods, it is possible to combine a very strong continuous copper alloy matrix structure with a very high lead content, and to alloy the lead-rich constituent with sufficient tin to make it resistant to corrosion. SAE 485 is used principally for bushing and bearing applications that involve alignment, shaft surface finish, or unusual dirt contamination problems.

Mechanical Properties of Copper-Base Bearing Alloys. Table 11 shows the ranges of mechanical strength properties that are exhibited by copper-base bearing alloys, according to alloy families and forms as listed in Table 10. Indentation hardness tests provide the most generally useful indications of behavior under compressive loads, and are the only standard strength tests that are applicable to all of the alloy forms. Conventional tensile and compression tests can be performed only on solid alloy bodies, which represent a relatively small fraction of total copper-base bearing alloy applications.

Table 11 Typical room-temperature mechanical properties of copper-base bearing alloys

(a) 0.1% offset

Test information of this kind is helpful in the material selection process as a supplement to information generated in dynamic rig tests and in actual service. Except in certain solid-alloy bearings and bushing applications, alloy strength and hardness values are rarely stated as absolute specification requirements.

Aluminum-Base Alloys

Successful commercial use of aluminum alloys in plain bearings dates back to about 1940, when low-tin aluminum alloy castings were introduced to replace solid bronze bearings for heavy machinery. Production of steel-backed strip materials by roll bonding (see the section "Roll Bonding Processes" in this article) became commercially successful about 1950, permitting the development of practical bimetal and trimetal bearing material systems using aluminum alloys in place of babbitts and copper alloys.

The ready availability of aluminum and its relatively stable cost have provided an incentive for continuing development of its use in plain bearings. Aluminum single-metal, bimetal, and trimetal systems can now be used in the same load ranges as babbitts, copper-lead alloys, and high-lead tin bronzes. Moreover, the outstanding corrosion resistance of aluminum has become an increasingly important consideration in recent years, and has led to widespread use of aluminum alloy materials (in the place of copper-lead alloys and leaded bronzes) in automotive engine bearings.

Designations and Compositions. Alloy designations and nominal compositions of the aluminum-base bearing alloys in most extensive commercial use are listed in Table 12. In these alloys, additions of silicon, copper, nickel, magnesium, and zinc function to strengthen the aluminum through solid-solution and precipitation mechanisms. Fatigue resistance and the opposing properties of conformability and embeddability are largely controlled by these elements and by the use of appropriate heat treatments. Tin and lead are instrumental in upgrading the inherently poor compatibility of aluminum. Cadmium is also used as an alloy addition for this reason. Silicon has a beneficial effect on compatibility in addition to its moderate strengthening effect. Although not well understood theoretically, this compatibility-enhancing mechanism is of considerable practical value. Silicon is used effectively in many alloys for this reason (usually in conjunction with tin, lead, or cadmium).

Microstructural Features. The cast low-tin alloys (numbers 9 through 11 in Table 12) all display similar microstructures consisting of equiaxed aluminum grains with $NiAl_3$, free silicon (if present), and free tin precipitated in the grain boundaries. Tin forms a nearly complete envelope around each aluminum grain. The copper and magnesium are mostly or completely in solid solution in the aluminum and are not visible under the microscope. Microstructures of the wrought low-tin, intermediate-tin, and high-tin alloys exhibit the expected effects of rolling and annealing, with the as-cast aluminum grains replaced by new recrystallized grains and the insoluble phases ($NiAl_3$, and silicon) uniformly distributed throughout. The original continuous grain boundary envelope of free tin assumes a completely new configuration, the tin now appearing as somewhat elongated, discontinuous "lakes." This characteristic structure, often termed "reticular," results in much greater ductility than that of the cast alloys.

Microstructures of the lead-aluminum alloys (numbers 3 and 4 in Table 12) exhibit a recrystallized aluminum matrix with a fine uniform dispersion of free silicon. The lead is present as thin stringers or ribbons of the lead-tin constituent, elongated in the rolling direction. During recrystallization, this constituent does not coalesce into lakes as does free tin, and the ribbon-like configuration persists in finished bearings. The effectiveness of the modest lead concentrations in these alloys in imparting surface compatibility probably is related to the favorable orientation of the lead-tin ribbons relative to the bearing surface.

The wrought tin-free alloys (numbers 16 through 20 in Table 12) display very simple microstructures, consisting of a recrystallized aluminum matrix with the soluble strengthening additions (copper, zinc, and magnesium) in solid solution. Insoluble phases ($NiAl_3$, silicon, cadmium, and lead) are present in fine and uniform dispersion.

Mechanical Properties of Aluminum-Base Bearing Alloys. Conventional mechanical properties are somewhat like microstructural features in that they are of more value in predicting the fabrication behavior of aluminum-base bearing alloys than in predicting their bearing performance. With the exception of solid aluminum alloy bearings, in which there is no steel back and where press-fit retention depends entirely on the strength of the aluminum alloy, mechanical properties of finished bearings are rarely specified, usually for control purposes only. Consideration of some of these properties (Table 13) does, however, contribute to an understanding of these alloys as a family of related engineering materials, and of their relationship to the better-known structural aluminum alloys in addition to the copper-base, tin-base, and lead-base bearing alloys discussed previously.

Table 13 Typical room-temperature mechanical properties of aluminum-base bearing alloys

Alloy family	Product form	Compressive yield strength[a]		Ultimate tensile strength		Hardness, HB

Tin-free alloys	Steel backed	. . .	. . .	. . .	. . .	35-65

(a) 0.2% offset

Product Applications. The majority of the current commercial applications of aluminum-base bearing alloys involve steel-backed bimetal or steel-backed trimetal bearings. To determine the most cost-effective aluminum material for any specific application, consideration should be given to the economic advantages of bimetal versus trimetal systems. The higher cost of the high-tin and high-lead alloys usually is offset by eliminating the cost of the lead alloy overlay plate. The cost effectiveness of the aluminum bimetal materials is clearly demonstrated by the fact that approximately 75% of the passenger car engines built in the United States use high-lead aluminum alloy bimetals for main and connecting-rod

bearings. In Europe and Japan, intermediate and high-tin aluminum bimetals similarly dominate passenger car engine bearing markets.

If the higher load capacity of a trimetal material is required, it then becomes important to select an aluminum liner alloy that provides adequate but not excessive strength, so that conformability and embeddability are not sacrificed unnecessarily. The tin-free alloy group (alloys 16 to 20 in Table 12) offers a wide range of strength properties, and the most economical choice usually is found in this group.

Silver-Base Alloys

Use of silver in bearings is largely confined to unalloyed silver (AMS 4815) electroplated on steel shells, which then are machined to very close dimensional tolerances and finally precision plated to size with a tin overlay of soft metal. The overlay may be lead-tin, lead-tin-copper, lead-indium, or in some cases, pure lead. As a bearing material, plated silver is invariably used with an overlay. Silver on steel with an overlay is regarded as the ultimate fatigue-resistant bearing material.

Silver was widely used during and after World War II in aircraft applications, where its high cost could be justified. With the phasing out of piston engines, however, the use of silver in bearings has greatly declined. Current applications are specialized, chiefly in the aircraft and locomotive industries. In view of the rapidly rising cost of silver, any increase in demand for this material would stimulate the search for a comparable less-expensive substitute.

Zinc-Base Alloys

The zinc-base alloys that have been used successfully for machinery bearings are standard zinc foundry alloys of the zinc-aluminum-copper-magnesium high-performance type. Tubular shapes made by conventional sand, permanent mold, and pressure die-casting methods are machined into bearings in the same way that solid bronze bearings are made. Most applications have been direct substitutions for solid bronze bearings; the substitutions are made primarily to reduce costs. Alloy designations, nominal compositions, and typical mechanical properties are shown in Tables 14 and 15 for the two predominant alloys in the United States.

Table 14 Designations and nominal composition of zinc-base bearing alloys

Designation		Composition, %			
UNS	**Trade**	**Zn**	**Al**	**Cu**	**Mg**
Z35631	ZA-12	88	11	1	0.025
Z35831	ZA-27	71	27	2	0.015

Table 15 Typical room-temperature mechanical properties of zinc-base bearing alloy

Z35840	ZA-27	Sand cast	330	48	421	61	4.5	90

(a) 0.1% offset

The high compressive strength and hardness values of these materials suggest greater load capacities than those of solid bronze and solid aluminum bearing materials (Tables 2 and 11). This is not the case in practice, however, largely because of the high rate at which the zinc alloys soften with increasing temperature. Maximum recommended running temperatures of 95 to 120 °C (205 to 250 °F) for the zinc-base alloys are approximately 100 °C (180 °F) below the temperature limits for copper-base and aluminum-base bearing alloys.

Microstructurally, these alloys display a eutectic or peritectic aluminum-zinc matrix, surrounding zinc-rich or aluminum-rich primary dendrites. Copper is in solid solution. Grain size varies greatly with casting method--from coarse in sand castings to finest in pressure die castings. Some experimental evidence associates the coarse sand cast structures with superior bearing wear resistance.

Because of their low cost, the zinc-base alloys will probably continue to replace copper-base alloys in certain bearing applications in construction, earth-moving, mining, and mill machinery markets. However, technical limitations with respect to high-temperature strength and corrosion resistance will prevent any massive movement away from bronzes and into zinc alloys.

Additional Metallic Bearing Materials

Additional commercially available metallic bearing materials include gray cast irons and cemented carbides.

Gray cast irons are standard materials for certain applications involving friction and wear (for example, brake drums, piston rings, cylinder liners, and gears). Cast irons perform well in such applications, and thus should be given consideration as bearing materials. Gray iron bearings have proved successful in refrigeration compressors where bearing pressures are <4500 kPa (<650 psi) for main bearings and <5500 kPa (<800 psi) for connecting rod bearings. Normally, the journals in refrigeration compressors are made either of steel (carburized and hardened to 55 to 60 HRC) or of pearlitic malleable or ductile iron (hardened to 44 to 48 HRC and having a surface finish of $\leq$0.3 μm, or 12 μin., root-mean-square, R_q. Because of occasional dilution of the oil with liquid refrigerant and heavy foaming of the oil, lubrication may become marginal for short periods of time. Fine-grain iron with uniformly distributed No. 6 (or finer) graphite flakes usually performs well during these periods. The bearings are often phosphate coated to improve their seizure resistance. This type of coating also creates a spongelike surface that promotes retention of oil.

For good wear resistance, gray cast iron should be pearlitic with randomly distributed graphite flakes. Cast irons have been heat treated to obtain martensitic structures for use as cylinder liners, but the benefits of such heat treatment have not been economically justifiable. Hardened cast iron has been used successfully as a material for the ways on machine tools.

Cemented Carbides. Extremely hard materials, including cemented tungsten carbides, titanium carbides, and other combinations have been used successfully for various specialized bearing and seal applications. In terms of the bearing performance characteristics listed in Table 1 these materials exhibit essentially zero conformability and embeddability, but rank high in strength, hardness, corrosion resistance, and compatibility. Cemented carbides have been of greatest interest in high-temperature aerospace applications, but have also been used to advantage in certain machinery and machine tool applications.

Nonmetallic Bearing Materials

Nonmetallic bearing materials are widely used for a variety of applications. They have many inherent advantages over metals, including better corrosion resistance, lighter weight, better resistance to mechanical shock, and the ability to function with very marginal lubrication or with no lubricant present at all. The major disadvantages of most nonmetallics are their high coefficients of thermal expansion and their low thermal conductivity characteristics. For many years, carbon-graphites, wood, rubber, and laminated phenolics dominated the field of nonmetallic bearing materials. In the early 1940s, development of nylon and polytetrafluoroethylene (PTFE, or Teflon) gave engineering designers two new nonmetallics with very unique characteristics, particularly the ability to operate dry.

A wide variety of polymer composites is now being used very successfully in bearing applications. The addition of fiber reinforcements and fillers such as solid lubricants and metal powders to the resin matrix can significantly improve the physical, thermal, and tribological properties of these plastics.

Casting Processes

Single-Metal Systems. Except for porous metal oil-impregnated bushings, all the single-metal systems listed in Table 2 are commercially produced by casting, either with or without subsequent mechanical working. Plate, strip, and sheet forms of commercial bronze, of low-lead and lead-free tin bronzes, and of aluminum-tin alloys are initially cast as ingots, slabs, or bars by static and continuous casting methods similar to those used for other brass and aluminum mill products. Subsequent rolling and annealing operations are also similar to those used for conventional mill products. Because of the

extreme hot shortness of leaded tin bronzes and aluminum-tin alloys, these alloys must be rolled either cold or at only slightly elevated temperatures, with frequent intermediate annealing.

The recrystallized wrought structures of bronze and aluminum-tin bearing alloys are substantially different from the initial cast structures, with respect to the configurations of the copper and aluminum phases and of the free-lead and free-tin phases. The improvements in ductility and forming characteristics that result from these structural changes are of great importance in subsequent bearing manufacturing operations. Bearing performance properties are not strongly affected by these changes. Both the as-cast and wrought forms of these alloys are in commercial use and are equally acceptable in bearing applications.

Tubular and cylindrical bronze, zinc, and aluminum-tin alloy shapes are produced by static, centrifugal, and continuous casting methods, and subsequently are machined into bearings. The high-lead bronzes are used only in the as-cast condition because of their low ductility and extreme hot shortness, which preclude any substantial amount of plastic deformation of cast shapes. Cast aluminum-tin alloy tubes can withstand a limited amount of cold work, however, and in some instances cold compression of 4 to 5% is employed to increase yield strength and improve press-fit retention in the finished bearings.

Bimetal Systems. Specialized casting methods are widely employed for producing bimetal bearing materials in both tubular and flat strip forms. Except for aluminum alloy systems (Table 3, classes 3 and 8), all bimetal systems in commercial use can, at least in principle, be produced by casting methods, and systems that incorporate tin and lead babbitt liners >0.1 mm (>0.004 in.) thick are universally produced by casting.

Babbitt Centrifugal Casting. Short tubular steel and bronze shapes (bearing shells) are commonly lined with tin or lead alloys by various forms of centrifugal casting. In these processes, a machined steel or bronze shell is first pre-heated and coated by immersion in molten tin or tin alloy. The prepared shell is then placed in a lathelike "spinner" and rotated at a controlled speed about its axis. Molten babbitt is admitted through one end and is uniformly distributed around the inside wall of the shell by centrifugal action. The molten layer then is cooled and solidified by spraying water against the outside of the rotating bearing shell. When properly controlled, these processes produce fine-grain liner layers of reasonably uniform thickness, completely bonded to the steel or bronze bearing-back material. Centrifugal casting methods are especially well suited to large-diameter thickwall bearings, which are made in relatively small quantities, and to full-round seamless bearings, which cannot be fabricated from flat strip.

Bronze Centrifugal Casting. Leaded tin bronzes also can be applied to the inner walls of steel shells by centrifugal casting. Various methods of shell preparation are employed, including both molten-salt and controlled-atmosphere pre-heating. Oxidation must be entirely absent from the inner wall of the steel shell for complete metallurgical bonding. Centrifugal casting of bronzes is most successful with alloys containing >3% Sn and $\leq$20% Pb. Outside this composition range, leaded tin bronze and copper-lead alloys are sensitive to lead segregation and consequent nonuniform "centrifuged" microstructures. Within these composition limits and under well-controlled process conditions, mechanically sound well-bonded bronze layers with reasonably uniform microstructures can be produced.

Bronze Gravity Casting. All copper-lead alloys and leaded bronzes containing $\leq$35% Pb can be successfully cast in and bonded to steel shells by gravity casting methods, in which centrifugal forces are not a factor. In these processes, a core usually is used to form an annular space inside the shell, into which molten bronze or copper-lead alloy is poured. Several different processes of this kind are in commercial use, utilizing a variety of preheating methods, core materials, pouring methods, and quenching procedures.

As in centrifugal casting, absence of oxides on the inner shell wall is necessary for complete bonding of the alloy layer to the steel back. Liner microstructures produced by gravity shell casting methods generally are more uniform than those obtained by centrifugal casting. For low-tin and high-lead compositions, gravity casting is preferred because of the absence of centrifuging effects on the solidifying alloy.

Babbitt Strip Casting. Steel-backed tin alloy and lead alloy bearing strip materials are commonly produced by continuous casting in specially designed process lines in which separate cleaning, etching, hot tinning, liner-alloy casting, and quenching operations are carried out continuously on a moving steel bearing-back strip. One or more in-line machining operations may also be incorporated so that the strip emerges with a closely controlled thickness, suitable for bearing fabrication.

Bronze Strip and Slab Casting. The oldest commercial processes for producing steel-back copper-lead and leaded bronze bearing strip also utilize continuous casting on a moving steel strip. Steel preheating, alloy casting, and quenching operations are performed under a strongly reducing atmosphere to ensure freedom from oxidation. Some in-line machining also can be done, but the cast strip usually is machined in a separate line for close control of thickness. Additional cold rolling and annealing operations are also employed--particularly with the low and medium lead-tin bronze alloys, in which recrystallized structures are frequently preferred for their superior fabrication properties.

Strip casting of copper alloys is a difficult technology that requires close process control, a high level of operator skill, and relatively expensive special-purpose equipment. It is used by only a few bearing manufacturers, but with considerable commercial success. It is employed not only for thin-gage coiled materials but also for heavy-gage slabs with steel thicknesses as great as 15 mm (0.60 in.).

Trimetal Systems. Trimetal materials with relatively thick surface layers (Table 4, classes 1, 2, and 3) are used mostly in large bearings. These bearings are produced in relatively low volumes from steel shells initially lined by casting with copper-lead alloys or bronze. After intermediate machining to remove excess liner alloy, such shells are commonly relined with tin or lead babbitt by centrifugal casting. The methods used are essentially the same as those for casting in bare steel or solid bronze shells.

Powder Metallurgy Processes

Single-Metal Systems. The only commercial use of powder metallurgy (P/M) methods for making single-metal bearing materials is in the fabrication of copper-base and iron-base porous metal bushings, which are subsequently impregnated with oil. The methods used are similar to those for making structural P/M shapes (that is, pressing in a closed die and sintering under a reducing atmosphere). Bars, tubes, and finished parts are made in this way. Post-sinter coining and repressing operations are frequently used to control final dimensions of finished parts.

Bimetal and Trimetal Systems. No powder metallurgy processes that use lead-base or tin-base bearing alloys are in commercial use nor are there at present any commercially developed processes for lining bearing shells by means of P/M methods. In the manufacture of steel-back copper-lead alloy and leaded bronze strip, however, P/M methods are employed more extensively than any other method.

Continuous Sintering Process. A wide variety of steel-back copper alloy materials, including counterparts of all of the cast copper-lead and leaded bronze bearing alloys (Table 3, class 4), can be produced by continuous sintering on a steel backing strip. In these processes, prealloyed (PA) powder particles are spread uniformly onto moving steel strip. As the strip passes through a furnace under a reducing atmosphere, the particles become sintered together, forming an open grid bonded to the steel strip. After cooling, this bimetal is rolled to densify the liner alloy and then resintered to develop complete interparticle and alloy/steel bonds. After resintering, the strip material may receive further rolling--to attain finish stock size, and sometimes to strain harden the alloy liner for increased strength.

Strip sintering technology makes possible the production of steel-core "sandwich" material, which is especially suitable for applications requiring two bearing surfaces (such as in some thrust washers). In this instance, powder spreading, sintering, cooling, and rolling are repeated on the opposite side, after which the strip is finally resintered. Sintered strip for most automotive and truck bearing applications is processed in coils $\leq$5mm ($\leq$0.2 in.) in overall thickness. Thick-wall materials with steel layers up to about 16 mm ($\frac{5}{8}$ in.) thick also can be processed into flat slab lengths.

Impregnation and Infiltration. Both bimetal and trimetal bearing materials also can be made by impregnation or infiltration of a lower-melting lead alloy into a layer of sintered copper alloy powder. In impregnation, a bilayer strip made from PA copper-lead alloy or leaded bronze powder is immersed in a bath of molten lead-tin alloy heated above the melting point of lead. During immersion, some of the lead at the surface of the strip is replaced by the lead-tin alloy. In infiltration, the copper alloy powder layer is free-sintered and not compacted after sintering. The open-grid sintered layer is then infiltrated with material having a lower melting temperature than that of the grid alloy.

The infiltrant is usually molten lead or a lead alloy but it can be a nonmetallic material such as PTFE, which can be introduced in paste or slurry form. A very useful class of self-lubricating trilayer structures is produced commercially in this way; the PTFE-base infiltrant also forms a thin low shear strength surface film in these structures.

Powder Rolling. One very useful application of direct powder rolling that has been developed commercially in the plain bearing industry is production of an aluminum-lead alloy strip for subsequent bonding to a steel back (see third item under class 3 in Table 3). In this method, PA lead-aluminum powder and unalloyed aluminum powder are fed simultaneously in separate streams to a powder rolling mill and continuously compacted into a bilayer aluminum strip. After sintering, this strip is roll bonded to low-carbon steel, with the unalloyed aluminum bonding layer next to the steel. This steel-back strip is used as a bimetal material for bearing applications where the unit loading is beyond the capability of tin or lead babbitt bimetal material.

Roll Bonding Processes

Virtually all commercial manufacturer of bimetal aluminum alloy bearing strip materials (see Table 3, class 3) is currently done by roll bonding the liner alloy to a steel backing strip. Both batch and continuous processes are employed, the latter being favored for economical high-volume processing of lighter-gage material.

In all roll bonding processes, whether batch or continuous, very clean aluminum and steel surfaces are forced together under intense pressure in a rolling mill, so that solid-phase bonding (cold welding) can occur between the two metals at many sites in the interface. Heat, which may be applied simultaneously with pressure in hot rolling and subsequently in postroll annealing, serves to develop complete diffusion bonding from the initial weld sites and to recrystallize the aluminum alloys so that the final bimetallic strip product exhibits useful liner-alloy ductility and complete bonding.

Tin-aluminum alloys usually are not bonded directly to steel because of undesirable interactions between the free tin constituent and the steel backing. A layer of electrolytic nickel plating on the steel surface is commonly used to alleviate these effects with both low-tin and high-tin alloy compositions.

Another method commonly used with tin-aluminum alloys employs a tin-free aluminum interlayer. This is accomplished by the use of Alclad tin-aluminum alloy strip. The tin-free cladding layer serves as the bonding surface and is present as a distinct bond interlayer in the finished bimetal strip.

Direct roll bonding to steel is most commonly employed with tin-free aluminum alloys (fifth item under class 3, Table 3) and with lead-aluminum strip materials.

Electroplating Processes

Plated Overlays. Lead alloy surface layers (overlays) whose thickness must be limited to <0.05 mm (<0.002 in.) (Table 4, classes 4 to 12) are most commonly produced by electroplating the lead alloy on bimetallic bearings that have previously been finish machined. Specially designed plating racks are used to ensure uniform distribution of plating current over the bearing surface. With close control of current, critical dimensional tolerances often can be maintained so precisely that no machining of the electrodeposited alloy surface is required. One manufacturer has commercialized a process in which the lead alloy electroplating is applied continuously to precision-rolled bimetal strip. In this process, all forming and machining operations are done after electroplating.

Electroplated lead babbitts comprise booth binary lead-tin and ternary lead-tin-copper compositions, all of which are commercially codeposited from fluoborate electrolytes. To ensure against bond and plate defects, extreme care is exercised in preparing the basis metal.

In addition to cleaning and etching treatments, preplating basis-metal preparation usually includes deposition of one more very thin metallic interlayers. A thin layer of nickel is most frequently used over copper-lead alloys and bronzes to prevent diffusion of tin from the plated surface layer into the copper basis metal. Copper is most often used over aluminum alloys to ensure complete adhesion of the plated lead alloy layer, and nickel sometimes is plated over the copper to prevent diffusion of tin from the lead alloy layer into the copper layer.

Binary lead-indium alloy overlays are also used with copper-lead and leaded bronze intermediate layers. These alloys are produced by electroplating separate layers of pure lead and pure indium and subsequently diffusing the indium into the lead in a low-temperature heat treatment operation. In this case, no diffusion barrier is required between the overlay and the intermediate alloy layer.

Plated Silver Intermediate Layers. Pure silver and silver-lead alloy bearing liners are applied to steel shells by electrodeposition from cyanide plating baths. Final machining usually is done after plating, leaving a substantially thick

layer (typically 0.25 to 0.38 mm, or 0.010 to 0.015 in.) of bonded silver liner material. Although as-plated thickness tolerances are not critical, special racking and masking techniques are employed to restrict plating to the surfaces where it is required and to eliminate local concentrations of high current density. If the structure of the plated layer is to be uniform, and the bond strength of the liner uniformly high, the steel basis metal must be prepared very carefully and plating-bath compositions and cleanness must be properly controlled. Although the basic principles involved in silver plating of bearing liners are the same as for decorative silver plating, the unusually thick deposits involved (normally >0.50 mm, or 0.020 in.) and the extremely high quality requirements for bond and plated-metal soundness have led to development of several unique operating and control practices.

Bearing Material Selection

It must be emphasized that selection of a bearing material system for a specific application and of a mechanical design for the bearing itself are closely interrelated processes. Neither process is entirely straightforward, neither can be approached independently, and both require a good understanding of other interacting components of the machine system.

Although this article considers the principles involved in bearing operation, it has not attempted to present a detailed discussion of mechanical design factors. The reader should therefore not expect to make final decisions on materials for specific applications on the basis of this text alone.

Most manufacturers of plain bearings have experienced engineering staff personnel available to aid potential users with both mechanical design and material selection. Because of the wide material selection offered by most of these experienced specialized producers and their background of experience in practical applications, full advantage should be taken of the engineering services such sources can provide.

Friction and Wear of Hardfacing Alloys

Paul Crook, Haynes International, Inc.; Howard N. Farmer, Consultant

Introduction

HARDFACING may be broadly defined as the application of a wear-resistant material, in depth, to the vulnerable (or worn) surfaces of a component by a weld overlay or thermal spray process. This discussion deals with the weld overlay materials used to resist wear; the thermal spray materials are covered in the article "Thermal Spray Coatings" in this Volume.

The weld overlay materials fall into five categories:

- Build-up alloys
- Metal-to-metal wear alloys
- Metal-to-earth abrasion alloys
- Tungsten carbides (for extreme earth sliding and cutting wear)

- Nonferrous alloys

Out of a total hardfacing alloy market of about 18 × 10^6 kg (40 × 10^6) per annum, it has been estimated that the first four categories, which are iron-based, account for about 90% by weight, but only about 75% by dollar volume.

The build-up alloys (which are essentially highly alloyed steels) are not designed to resist wear but to return a worn part back to, or near, its original dimensions and to provide adequate support for subsequent layers of true hardfacing materials. However, these alloys are sometimes used as wear-resistant materials under mild wear conditions. Typical examples of applications where build-up alloys are used for wearing surfaces include:

- Tractor rails
- Railroad rail ends
- Steel mill table rolls
- Large slow-speed gear teeth

The metal-to-metal wear alloys are martensitic air-hardening steels that, with care, can be applied (without cracking) to wearing areas of machinery parts. Typical applications of this alloy family include:

- Undercarriage components of tractors and power shovels
- Steel mill work rolls
- Crane wheels

Most of the materials in the final three categories consist of hard particles within a metallic matrix, and, for many, it is the hard constituent that provides resistance to wear. The cobalt-base alloys are an exception in this regard because they exhibit resistance to a wider variety of wear forms, largely by virtue of the deformation and fracture characteristics of the cobalt-rich matrix.

The primary function of the metal-to-earth abrasion alloys and tungsten carbides is abrasion resistance. The metal-to-earth alloys are high-chromium white irons in which chromium carbides are formed during alloy solidification. The tungsten carbides are actually composite materials, and their use involves the transfer of discrete tungsten carbide particles (which in the welding consumable forms are encased in a steel tube) across the welding are and into the molten weld pool, where they are subsequently "frozen" into the overlay structure by the matrix formed from the melting of the steel tube.

The metal-to-earth alloys possess resistance to sliding and crushing (that is, low- and high-stress) abrasion on a moderate scale, whereas the tungsten carbides are intended for use under extreme sliding and cutting conditions. Typical applications for these material types include:

- Shovel teeth
- Rock crusher parts
- Plowshares
- Auger flights

The nonferrous hardfacing alloys are used in environments that are too aggressive for the ferrous hardfacing alloys or where high resistance to a specific type of wear (other than abrasion) is required. For the purpose of this article, they are classified as follows:

- Cobalt-base/carbide type
- Cobalt-and nickel-base/Laves type
- Nickel-base/boride type

- Bronze type

Also included in the discussion of the first of these types are several substitute materials, some of which are iron-base, but share with the cobalt-base alloys resistance to a variety of wear conditions and corrosive media.

Whereas the ferrous hardfacing alloys and tungsten carbide composites find extensive use in agriculture, mining, construction, and the steel industry, the nonferrous alloys are typically used in the chemical processing, power, automotive, and oil industries, all of which require resistance to a hostile environment in addition to resistance to wear. The cobalt-base alloys are especially to deformation and chemical attack at high temperatures (500 °C < $T \leq$ 900 °C, or 930 °F < $T \leq$ 1650 °F) and are used to protect dies and guide rolls in the steel industry. Other common applications of the nonferrous hardfacing alloys include:

- Valve seating surfaces (both control valves and diesel exhaust valves
- Pump parts
- Extrusion screw flights
- Rock bit bearings
- Marine bearings
- Glass molding hardware

The discussion up to this point has been devoted to briefly introducing the five families of weld overlay material. It is now appropriate to distinguish, in a general way, between the individual family members. This is best done by considering that within each family (or category), several levels of abrasion resistance are available. Increasing abrasion resistance, however, is accompanied by increasing brittleness, which can cause cracking during cooling, after welding, or under impact loading in service. In certain situations (for example, seating surfaces in chemical control valves), a material with less than optimum abrasion resistance must be chosen in order to obtain a crack-free overlay or to ensure that the overlay does not crack in service.

This "abrasion level" concept is particularly applicable to the metal-to-earth alloys, the tungsten carbide composites, the cobalt-base/carbide-type alloys, and the nickel-base/boride type alloys. The level of abrasion resistance within these material groups is generally proportional to the carbon, hence carbide, or the boron content.

Although the cracking of weld overlays is of great concern in many applications, it may be desirable (for example, for the relief of residual stresses) for others. In the mining and construction industries, where brittle metal-to-earth abrasion alloys are used, relief of stresses prior to the use of equipment is important, the objective being to reduce the risks of underbead (substrate/overlay interface) cracking during service and the subsequent spalling of the overlay.

Several welding processes are used to apply the hardfacing materials. They range from the traditional (for example, oxyacetylene torch) to the new and sophisticated (for example, plasma-transferred arc, PTA, and synergic metal inert gas, MIG). To accommodate these different overlay processes, the hardfacing materials are available in a variety of forms. The most popular processes, and the forms most commonly associated with each process, are:

Weld overlay process	Consumable form
Oxyacetylene	Bare cast or tubular rod
Shielded metal arc (SMA)	Coated solid or tubular rod (stick electrode)
Gas tungsten arc (TIG)	Bare cast or tubular rod
Gas metal arc (MIG)	Tubular or solid wire
Open arc	Tubular wire (flux cored)
Submerged arc	Tubular or solid wire
Plasma-transferred arc (PTA)	Powder

In choosing the process to be used, the following factors are important:

- Deposition rate
- Level of dilution (the amount of substrate material intermixed with the overlay material during welding)
- Portability of equipment

To overcome the effects of dilution on wear properties, multiple layers are often employed.

Build-Up Alloys

Although designed specifically to bring worn parts back to (or close to) their original dimensions and to provide adequate support for subsequent layers of the high-chromium, white irons, and tungsten carbide composites, the build-up materials are sometimes used to resist combinations of impact and light abrasion (particularly where multiple layers and machinability are required). The build-up alloys fall into two categories: alloy steels and austenitic manganese steels. The alloy steel build-up materials are used with carbon steel and alloy steel substrates; the austenitic manganese steels are used for the joining, repair, and/or protection of manganese steel components.

The high strength of the austenitic manganese steels is the result of a synergism between manganese and carbon (Ref 1). In suppressing the formation of phases other than austenitic, manganese not only increases carbon solubility at lower temperatures but also encourages carbon supersaturation of the structure. Both high inherent strength and a high work hardening rate result from this.

Because the austenitic manganese steels are metastable, problems of carbide embrittlement tend to arise when the alloys are cooled slowly or reheated. Manganese steel components are therefore kept as cool as possible during the build-up (repair) process. Often, the bulk of the part is submerged in water during the welding process.

An overview of the abrasion and impact properties of the build-up alloys relative to the metal-to-metal wear alloys is presented in Table 1. Specific build-up alloy compositions are given in Table 2. In the austenitic manganese steels, chromium is added to increase strength but promotes the formation of embrittling carbides. Molybdenum and nickel, on the other hand, suppress the precipitation of embrittling carbides (molybdenum by modifying the type and geometry of carbides formed, and nickel by increasing the stability of the austenitic structure).

Table 1 Impact resistance and abrasion resistance properties of build-up alloys and metal-to-metal wear alloys

Substrate	Resistance[(a)]			
	Impact		**Abrasion**	
	Min	**Max**	**Min**	**Max**
Build-up weld overlay				
Carbon steel	4.0	4.5	0.5	1.0
Manganese steel	8.5	9.5	2.0	2.5
Metal-to-metal weld overlay				
Easy-machining steel	3.0	3.5	1.5	2.0
General-purpose steel	2.5	3.5	1.0	3.5
High-temperature steel	3.0	3.5	2.0	3.5

(a) On scale from 0 to 10, where 10 is optimum resistance property. Min, minimum; max, maximum

Table 2 Composition, hardness, and abrasion data for build-up alloys and metal-to-metal wear alloys

Alloy	Composition, wt%							Hardness, HRC	Abrasion, volume loss			
									Low-stress[c]		**High-stress[d]**	
	Fe	**Cr**	**C**	**Si**	**Mn**	**Mo**	**Ni**		**mm^3**	**in.^{3} × 10^{-3}**	**mm^3**	**in.^{3} × 10^{-3}**
Build-up weld overlay												
EFe 1[a]	bal	2	0.1	1.0	1	1.5	. . .	37	88	5.4	49	3.0
EFeMn-C[a]	bal	4	0.8	1.3	14	. . .	4	18	65	4.0	57	3.5
EFeMn-Cr[a]	bal	15	0.5	1.3	15	2.0	1	24	93	5.7	46	2.8
Metal-to-metal weld overlay												
EFe2[a]	bal	3	0.2	1.0	1	1.0	1	48	54	3.3	66	4.0
EFe3[a]	bal	6	0.7	1.0	1	1.0	. . .	59	60	3.7	68	4.1
ER420[b]	bal	12	0.3	1.0	2	. . .	. . .	45	84	5.1	62	3.8

(a) Two-layer SMA deposit process.

(b) Two-layer SAW deposit process.

(c) Dry sand/rubber wheel test (ASTM G 65, Procedure B):load 13.6 kg (30 lb); 2000 rev.

(d) Slurry/steel wheel test(ASTM B 611, modified):load 22.7 kg (50 lb); 250 rev

Room-temperature hardness and low- and high-stress abrasion data for the compositions are also listed in Table 2. The low-stress data were generated using the dry sand/rubber wheel (ASTM G 65) test, and the high-stress results were produced using the slurry/steel wheel (ASTM B 611, modified) test. The high-stress test is the more severe, and the volume losses reported are for only 250 rev of the steel wheel (as compared with 2000 rev of the rubber wheel in the low-stress test).

As may be deduced from these data, as-deposited hardness is a poor indicator of low- or high-stress abrasion resistance for these alloys.

Metal-to-Metal Wear Alloys

Alloys in the metal-to-metal category (commonly referred to as machinery hardfacing alloys) are martensitic, air-hardening steels that can be applied several layers thick and can be finish machined (although with some difficulty) if adequate equipment is used. They are recommended for wearing, industrial, heavy-duty, nonlubricated parts. These materials are also sometimes referred to as "super build-up" alloys. If a machined finish is required, three layers are generally applied, with the assumption that the top layer will be removed during machining. A single layer is usually inadequate because of the effects of substrate/overlay intermixing (dilution).

Typical compositions and properties of the metal-to-metal wear alloys are presented in Tables 1 and 2. As with the build-up alloys, there appears to be no correlation between room-temperature hardness and abrasion properties.

In hostile environments, a high chromium content is beneficial. ER420 (American Welding Society, AWS, classification), and modified versions containing nickel, molybdenum, and niobium (or vanadium), are therefore the natural choice when high temperatures and mildly corrosive environments are encountered. For applications using steel mill hot-work rolls (which demand considerable hot hardness, resistance to oxidation, and resistance to thermal fatigue) both ER420 and EFe3 have been found suitable. Other applications for the metal-to-metal wear alloys in Table 2 include tractor rollers and crane wheels (EFe2), pincer guide shoes (EFe3), and blast furnace bells (ER420).

Metal-to-Earth Abrasion Alloys

The high-chromium irons encompass a wide range of compositions in which chromium may vary between approximately 6 and 35 wt%, and carbon may vary from about 2 to 6 wt%. Other possible alloying additions include molybdenum, manganese, and silicon.

The most important microstructural feature in the high-chromium irons, at least from a wear standpoint, is an M_7C_3 carbide, which forms in abundance during solidification and contains chromium, iron, and (if present) molybdenum. The matrix around these carbide particles can be austenitic, pearlitic, or martensitic (Ref 2). In general, the austenitic alloys rely on manganese for austenite stability.

As mentioned in the introduction of this article, carbon content is a good indicator of abrasion resistance for this class of materials. To illustrate this fact, low- and high-stress data are plotted for selected alloys in Fig. 1. This information was generated by the use of six different alloys (open arc/flux-cored wires) and nine different sets of welding parameters (Ref 3). The carbon contents referred to in the figures are those of the second layer of the two-layer overlays tested. The use of a shaded zone, rather than a line, indicates that there was considerable scatter in the data (particularly at the lower carbon contents, in the case of high-stress abrasion). The test methods and parameters were identical to those described in the section "Build-Up Alloys" in this article.

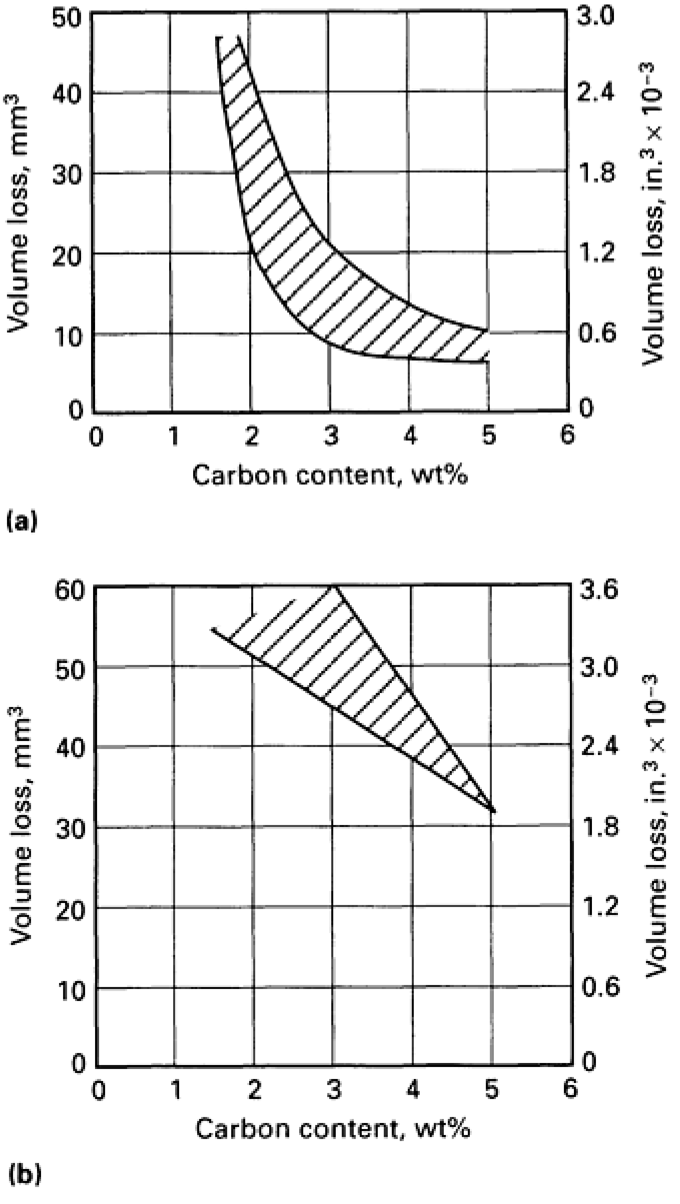

Fig. 1 Plot of volume loss versus carbon content for high-chromium iron metal-to-earth abrasion alloys. (a) Low-stress condition. (b) High-stress condition. Source: Ref 3

At high carbon and chromium levels, the formation of a hypereutectic microstructure, containing large, spinelike carbide particles (with a hexagonal cross section), is favored. At lower carbon and chromium contents, the microstructure is hypoeutectic. The microstructures of three-high-chromium irons (as deposited by the open arc welding process) are shown in Fig. 2. The nominal compositions of the same three alloys are presented in Table 3. As can be seen, ERFeCr-A3 (at a chromium content of 11 wt% and a carbon content of 2.6 wt%) exhibits a hypoeutectic (primary austenite) microstructure. The other two alloys, ERFeCr-A4(Mod) (29Cr/3.5C) and ERFeCr-A2 (28Cr/4.3C), possess a hypereutectic (primary carbide) structure. In Fig. 2, the large, spinelike carbides are shown in cross section.

Table 3 Composition of metal-to-earth abrasion alloys

Alloy	Composition, wt%

ERFeCr-A4(Mod)	29	3.5	1.1	0.9	. . .	2.6	0.7	bal

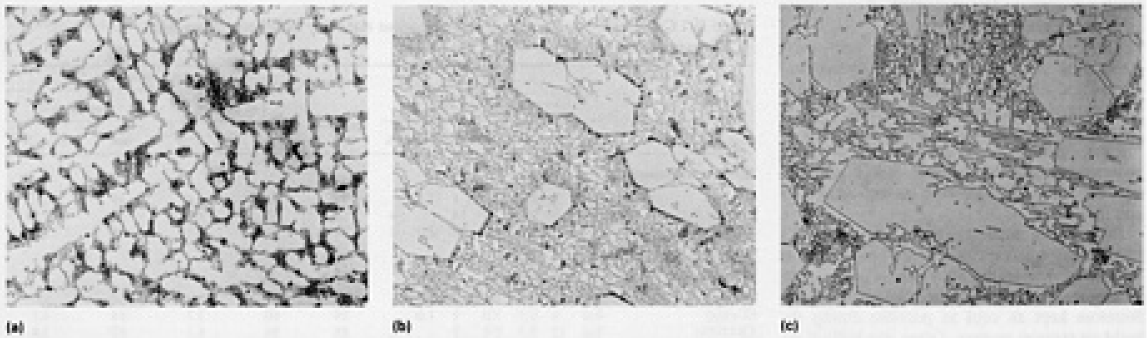

Fig. 2 Microstructure of high-chromium iron metal-to-earth abrasion alloys hardfaced with two-layer open arc deposit welding process. (a) ERFeCr-A3. (b) ERFeCr-A4(Mod). (c) ERFeCr-A2. 300×

In addition to M_7C_3, deposits of ERFeCr-A2 contain small quantities of M_6C and deposits of ERFeCr-A4(Mod) contain small quantities of both M_6C and M_3C. With regard to the matrix, both ERFeCr-A3 and ERFeCr-A4(Mod) exhibit a face-centered cubic (fcc) austenitic structure as deposited. ERFeCr-A2 is largely austenitic but may also contain small quantities of ferrite or martensite. The presence of martensite in the matrix structure of a high-chromium iron is believed to be beneficial to its high-stress abrasion resistance because of the additional support it provides to surface carbides.

For a given hardfacing consumable, deposit (overlay) microstructure is strongly influenced by the welding process and parameters used. Factors of concern, in this regard, include:

- Overlay/substrate intermixing
- Changes in composition due to losses in the arc
- Deposit cooling rate

With regard to industrial applications of the metal-to-metal abrasion alloys, the low-carbon (2 to 3% C) hypoeutectic materials are usually selected for situations involving moderate abrasion and impact, whereas the higher carbon (4 to 6% C) hypereutectic alloys are used in applications involving severe abrasion and little or no impact. Specific uses include:

- Crushers cones and pump casings (ERFeCr-A3)
- Bulldozer blades and crusher hammers [ERFeCr-A4(Mod)]
- Coal pulverizer liners and gravel pumps (ERFeCr-A2)

Tungsten Carbides

In contrast to the other weld overlay materials, the tungsten carbide composites do not rely upon the formation of suitable hard phases during weld pool solidification. Instead, these overlay materials rely on the transfer of tungsten carbide particles from the welding consumable to the overlay. It is important, therefore, to limit the heat input of the welding process in order to prevent melting of the tungsten carbide particles. If the tungsten carbide particles melt, they mix with

iron to form much softer iron-tungsten carbides, thus reducing abrasion resistance. For this reason, oxyacetylene deposits usually exhibit higher abrasion resistance than arc-welded tungsten carbide overlays.

An advantage of the tungsten carbide composites is that the size of the hard particles in the overlay can be controlled. This is important because abrasion resistance is dependent upon the size relationship between microstructural features (such as carbides) and the abrading particles. It is believed that, if the abrading particles are large in comparison to the microstructural particles, then, after a running-in period (during which the softer matrix material at the surface is worn down), the abrading particles ride over the hard microstructural outcrops. On the other hand, if the abrading particles are small in comparison to the microstructural particles, it is believed that the opportunity exists for wear of the matrix around the microstructural particles. Eventually, these may drop out, having played only a small in resisting abrasion.

The tungsten carbide particles themselves are typically manufactured by the melting of tungsten and carbon in a graphite crucible. During subsequent cooling, a two-phase mixture of WC and W_2C is formed. After crushing and screening (size selection), this material is incorporated into a tabular welding product with a carbon steel sheath.

Several tungsten carbide composites are available in a variety of tabular product forms. Popular compositions are 38, 50, 55, and 60 wt% tungsten carbide, with the carbon steel tube making up the balance. For each composition, several carbide size ranges are available. As an example, for the 60% WC oxyacetylene welding consumable, four mesh size ranges are available:

AWS designation	Mesh size range
RWC-12/20	12-20
RWC-20/30	20-30
RWC-30/40	30-40
RWC-40/120	40-120

The same composition is also available in flux-coated form for shielded metal are welding (SMAW) and as a continuous wire (with an internal flux) for open arc welding.

Tungsten carbide composites generally possess very high resistance to abrasion and very low impact strength. Performance in a given situation is dependent upon:

- Carbide volume fraction
- Size relationship between the carbides and the abrasive medium
- Welding technique applied

Important factors are the distribution of carbides in the overlay (because the particles tend to sink, turbulence in the molten weld pool is an advantage), and the amount of carbide dissolution and reprecipitation in the steel matrix during welding. Impact strength generally decreases with increasing carbide volume fraction.

Table 4 relates tungsten carbide composites and the previously mentioned alloys on the basis of low-stress and high-stress abrasion data (generated under identical test conditions). These values should be compared with the values in Table 2 and Fig. 1. Photomicrographs of the test deposits are shown in Fig. 3. Noteworthy features include:

- The difference in size of the tungsten carbide particles in the two materials
- The extent to which secondary carbides have precipitated within the matrix

Table 4 Abrasion data for tungsten carbide composites

Material		Abrasion, volume loss

The tungsten carbide composites have been used to solve a wide variety of industrial sliding and drilling abrasion problems. Some of the common applications are plowshares, ditchdigger teeth, ripper teeth, and oil well drilling tools. For extremely hostile environments, some nonferrous tungsten carbide products (cobalt- and nickel-base products in the form of bare cast rods) are available. Also, several alternative composite materials, utilizing other carbides (for example, vanadium, titanium, or niobium), are available that have the advantage of creating a more homogeneous deposit because of their lower densities.

Nonferrous Alloys

Nonferrous hardfacing alloys are used either for high resistance to specific types of wear (other than abrasion), or for wear resistance (including abrasion) in environments that are too corrosive or beyond the service temperatures of ferrous alloys. The cobalt-base alloys and bronzes are particularly resistant to galling and to those wear processes involving microfatigue as the degradation mechanism (such as cavitation erosion). The cobalt-base alloys possess high resistance to deformation at temperatures in excess of 750 °C (1380 °F).

Cobalt-Base/Carbide-Type Alloys. Table 5 lists typical compositions of the nonferrous hardfacing alloys. The chief difference between the various cobalt-base/carbide-type alloys is in carbon content (hence, carbide volume fraction, room-temperature hardness, and level of abrasion resistance). Chromium-rich M_7C_3 is the predominant carbide in these alloys, although tungsten-rich M_6C is evident in those alloys having a high tungsten content, and chromium-rich $M_{23}C_6$ is common in the low-carbon alloys.

Low-stress abrasion, galling, and cavitation erosion data are presented for many of the nonferrous hardfacing alloys in Fig. 4, 5, and 6. Figure 4 relates the carbon content and the resistance to low-stress abrasion for the cobalt-base/carbide-type alloys (ERCoCr-A, -B, -C, and -E). From Fig. 5 and 6, it is evident that the cobalt-base matrix (solid solution) is responsible for the excellent self-mated sliding properties and cavitation erosion resistance of these alloys. Additional information is available in the article "Friction and Wear of Cobalt-Base Wrought Alloys" in this Volume.

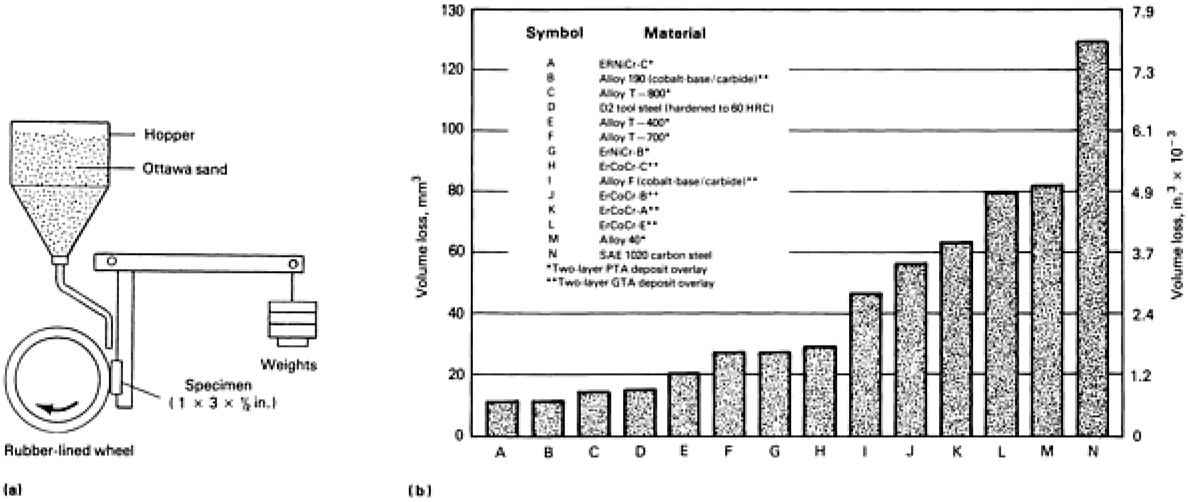

Fig. 4 Comparison of hardfaced nonferrous alloys to tool steel and carbon steel reference materials using ASTM G 65 low-stress abrasion test. (a) Schematic of G 65 dry sand/rubber wheel test apparatus. (b) Low-stress abrasion test data. G 65 test parameters: procedure B; room temperature; 13.6 kg (30 lb) load; quartz grain sand diameter of 212 to 300 μm (8.48 to 12 mil); 2000 rev at 200 rev/min; 390 g/min (0.86 lb/min) feed rate

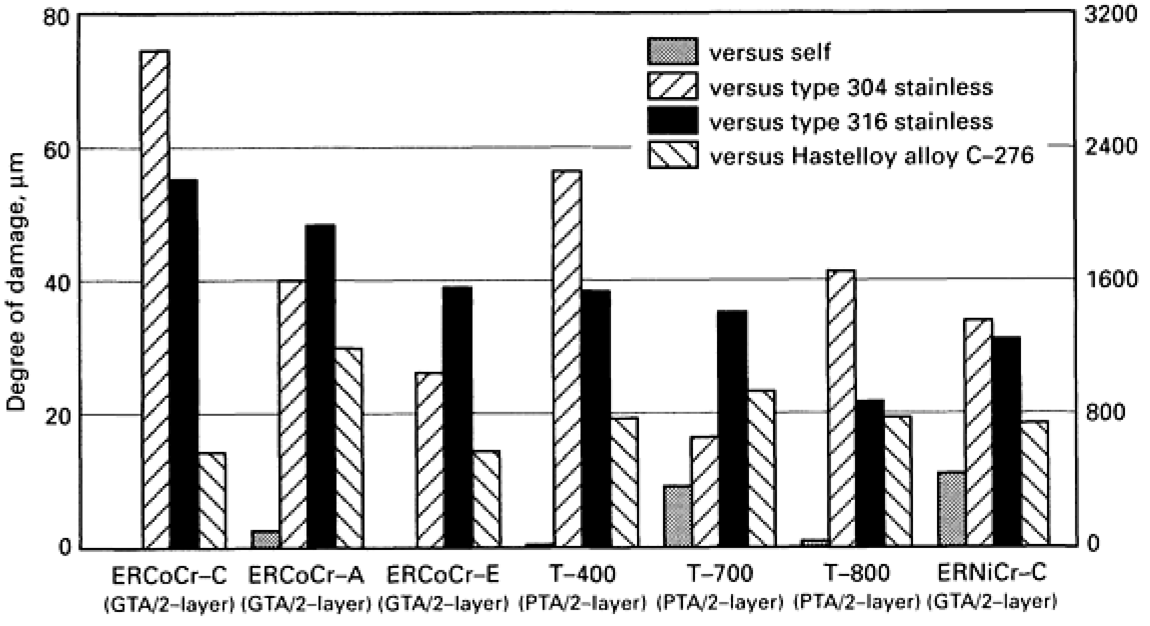

Fig. 5 Galling property evaluation of nonferrous alloys versus selected alloys (itself, stainless steels, and a nickel-molybdenum-chromium alloy). Data obtained using pin-on-block test with following parameters: 2722 (6000 lb) load; 10 strokes through 120° arc. GTA, gas tungsten arc

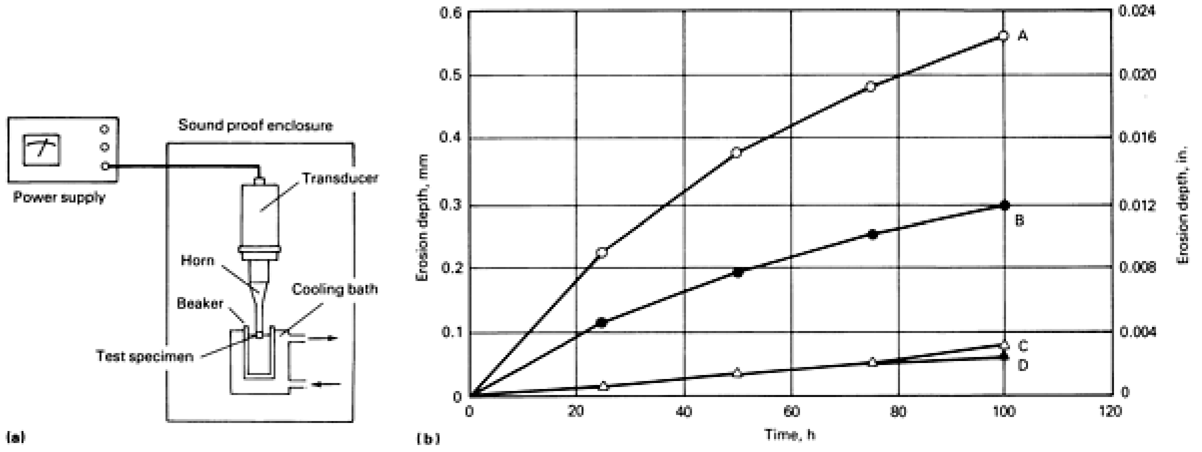

Fig. 6 Comparison of hardfaced nonferrous alloys to a stainless steel and a nickel-molybdenum chromium alloy using ASTM G 32 vibratory cavitation test. (a) Schematic showing G 32 test apparatus, (b) Cavitation erosion test data. G 32 test parameters: medium, distilled water; test temperature, 16 °C (61 °F); vibration, 20 kHz frequency at 0.05 mm (0.002 in.) amplitude. A, type 410 stainless steel (hardness, 23 HRC); B, Hastelloy alloy C-276; C, ERCoCr-E (two-layer GTA deposit); D, ERCoCr-A (two-layer GTA deposit)

The low-stress abrasion data in Fig. 4 were generated using the ASTM G 65 dry sand/rubber wheel test. The vibratory cavitation test described in ASTM G 32 was used to generate the results given in Fig. 6. The results in Fig. 5 relate to a pin-on-block galling test (Ref 4).

Photomicrographs of plasma-transferred arc (two-layer) deposits of three cobalt-base/carbide-type alloys are shown in Fig. 7. The differences in carbide volume fraction and geometry are evident from these photomicrographs.

Iron and Nickel Substitutes for Cobalt Compositions. Because of the relatively high cost of cobalt, attempts have been made to design alternate materials, with iron and nickel as the predominant cobalt substitutes. The compositions of three such materials are given in Table 6. A comparison of the sliding wear properties of the cobalt-base/carbide-type alloys and these three alternate alloys, as a function of temperature up to 1000 °C (1830 °F), is presented in Fig. 8. From the data in Fig. 8, it is evident that cobalt content is a very important factor up to ~750 °C (~ 1380 °F), above which oxide glaze formation is observed.

Table 6 Composition of alternate alloys to replace cobalt-base/carbide-type alloys

High-silicon stainless steel									

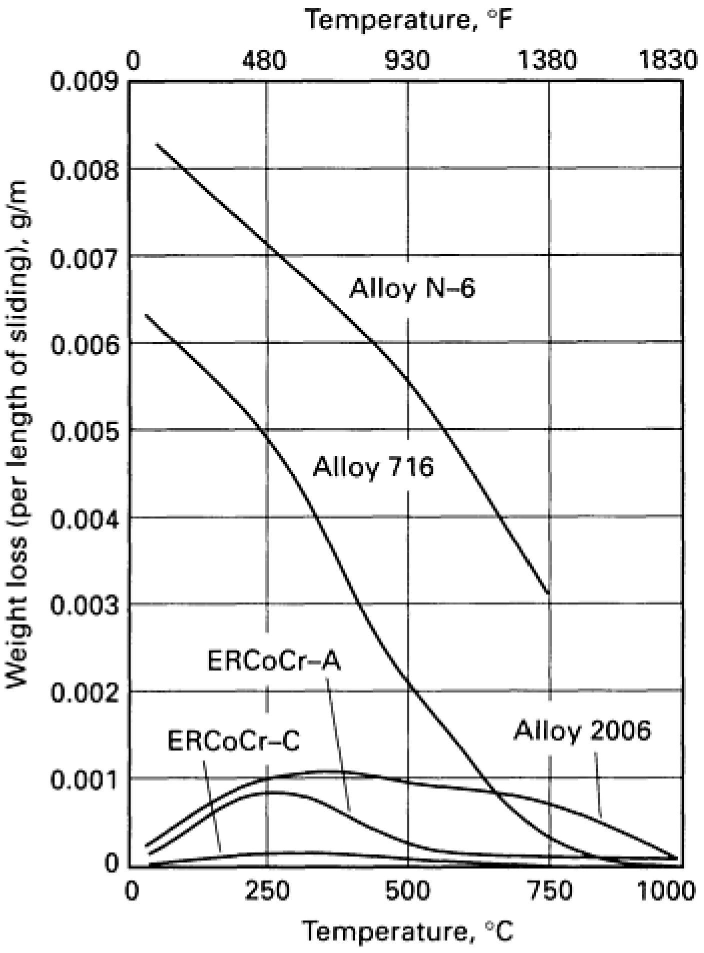

Fig. 8 Plot of wear rate versus temperature to compare sliding properties of cobalt-base/carbide-type alloys and selected alternate alloys, all of which have been GTA deposit hardfaced. Test conditions include pressure of 21 MPa (3 ksi) and velocity of 8 mm/s (0.3 in./s).

The information in Fig. 8 is also useful because it indicates a maximum sliding wear rate for the cobalt-base hardfacing alloys (self-mated) at ~250 °C (~480 °F). During these (reciprocating) sliding wear tests (Ref 5), the coefficient of friction was monitored continuously. Not only was this parameter found to vary through each sliding cycle, but the values also drifted with test time (hence sliding distance). For reference, friction coefficient traces for ERCoCr-A, at 25, 500, and 1000 °C (75, 930, and 1830 °F), are shown in Fig. 9. Note that relatively high values were obtained in the early stages of testing at 1000 °C (1830 °F) (presumably during the time interval in which the oxide glaze was forming).

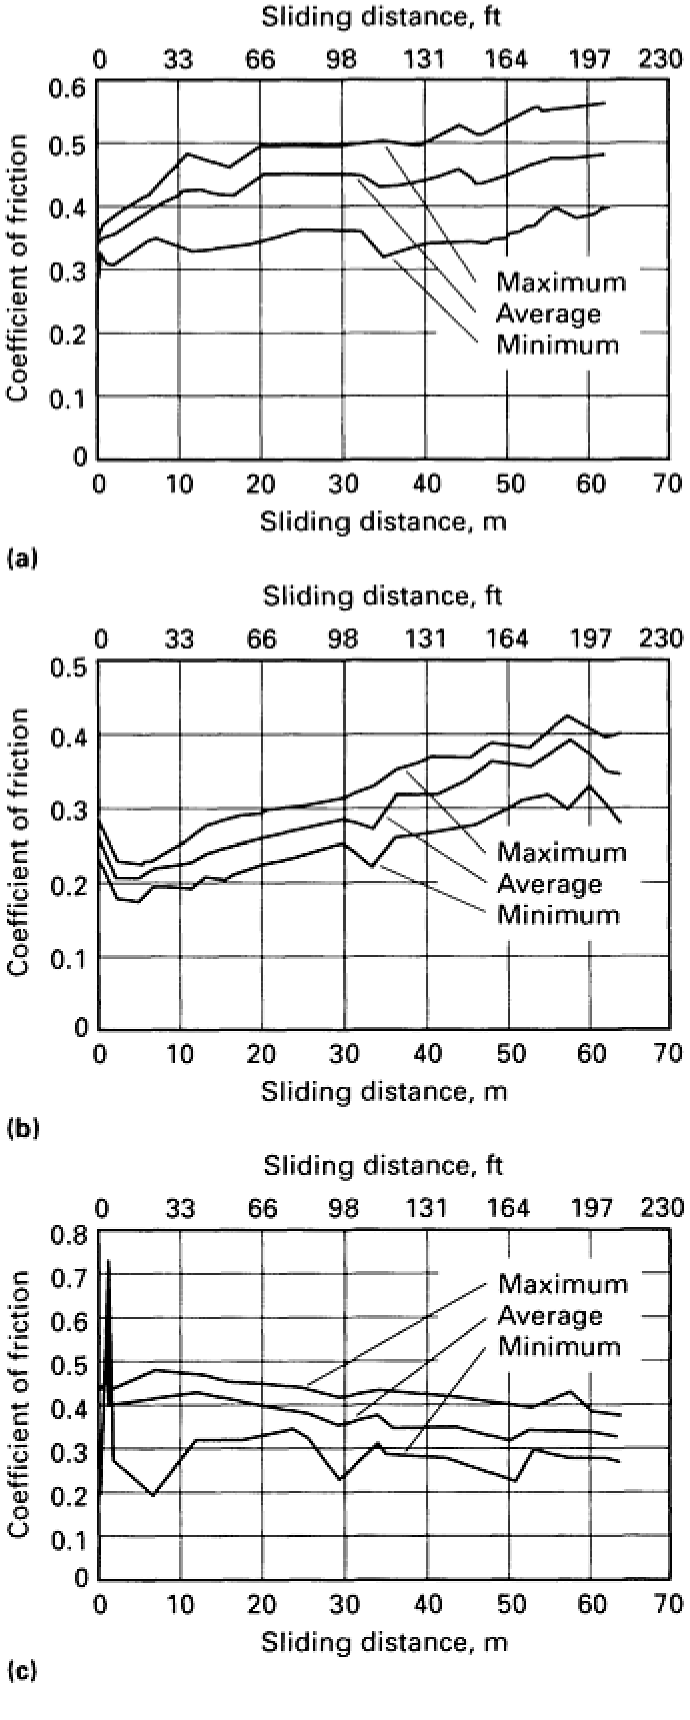

Fig. 9 Plot of coefficient of friction versus sliding distance for self-coupled ERCoCr-A (GTA deposit) hardfaced cobalt-base/carbide-type alloy as a function of test temperature. (a) 25 °C (75 °F). (b) 500 °C (930 °F). (c) 1000 °C (1830 °F). Test conditions include pressure of 21 MPa (3 ksi) and velocity of 8 mm/s (0.3 in./s).

High-Silicon Stainless Steel Alternate Material. Recently, several new high-silicon stainless steels have been introduced that may be considered as alternate materials. These exhibit identical anti-galling characteristics and possess equal resistance to cavitation erosion. Some of these have been developed for general use, and others for specific applications (for example, hydroelectric turbines and nuclear valves). Some are based on type 200 (manganese- and nitrogen-containing) austenitic stainless steel; others are based on type 300 stainless steel. One of these latter compositions is presented in Table 6. These high-silicon hardfacing alloys differ from the traditional cobalt-base/carbide-type alloys in terms of their corrosion resistance (they are better in some aqueous media and worse in others), their mechanical properties (particularly at high temperatures), and their thermal stability.

Laves-Type Alloy Compositions. Three cobalt- and nickel-base/Laves-type alloy compositions are presented in Table 5. In these materials, molybdenum and silicon are added at levels in excess of their solubility limit with the objective of inducing the precipitation of the hard (and corrosion-resistant) Laves phase (an intermetallic compound). Carbon is held as low as possible in these alloys to discourage carbide formation. The microstructure of alloy T-800 (two-layer PTA deposit) is shown in Fig. 10.

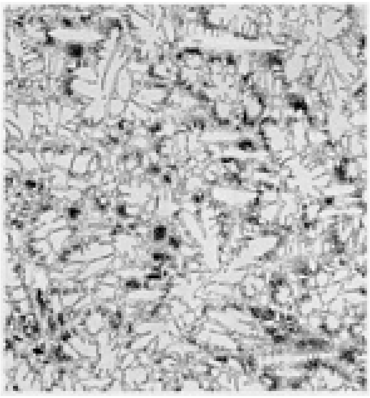

Fig. 10 Microstructure of Alloy T-800 (two-layer PTA deposit) cobalt-base/Laves-type nonferrous alloy. 200×

Because the Laves intermetallic phase is so abundant in these alloys, its presence governs all the material properties. Accordingly, the effects of the matrix composition in these alloys are less pronounced than is the case for the cobalt-base/carbide-type alloys, for example. The Laves phase is especially responsible outstanding abrasion resistance, but it severely limits the material ductility and the impact strength. In fact, it is difficult to attain crack-free overlays on all but the smallest components given adequate preheat. For this reason, these alloys have been more successful as thermal spray materials.

Nickel-Base/Boride-Type Alloys. Of all the hardfacing alloys, the nickel-base/boride-type alloys are microstructurally the most complex. The alloy compositions represent a progression in terms of iron, chromium, boron and carbon contents (Table 5). Iron content is largely incidental, allowing the use of ferrocompounds during manufacture. Together with nickel, the other three elements determine the level and type of hard face within the structure upon solidification, boron being the primary hard-face forming element (for which nickel and chromium compete) and carbon being the secondary hardphase former).

The chief purpose of silicon in the material is to provide, in conjunction with boron, self-fluxing characteristics. However, as an important matrix element and as a potential promoter of intermetallic precipitates, it also has a powerful influence on the wear properties of the alloys.

The actual phases that form in the nickel-base/boride-type alloys are listed in Table 7 on the basis of chromium content.

Table 7 Phases formed in nickel-base/boride-type alloys

Chromium content	Secondary phases		Dominant hard phase
	Compound formed	**Required conditions**	
Low (~5 wt%)	Ni_3Si	>3 wt% Si	Ni_3B
Medium (~15 wt%)	Ni_3Si	>2.5 wt% Si	Ni_3B and chromium boride (usually CrB, although Cr_2B and Cr_3B_2 may also be present)
High (~25 wt%)	Ni_3Si	>3 wt% Si	CrB and Cr_5B_3
All levels	. . .	. . .	Complex carbines of $M_{23}C_6$ and M_7C_3 types

Boron content influences the level of silicon required for silicide (Ni_3Si) formation. The higher the boron content, the lower is the silicon content required to form silicides.

The complexity of the nickel-base/boride-type alloy microstructure is evident in Fig. 11, which shows a two-layer PTA deposit of ERNiCr-C.

Fig. 11 Microstructure of ERNiCr-C (two-layer PTA deposit) nickel-base/boride-type nonferrous alloy. 425×

Because of the boride and carbide dispersions within their microstructures, the nickel-base/boride-type alloy exhibit excellent resistance to abrasion (ERNiCr-C, ERNiCr-B, and Alloy 40 in Fig. 4b). Low-stress abrasion resistance generally increases with boron and carbon contents, hence the hard-phase volume fraction for these materials. Although their performance is not as good under self-mated sliding as the cobalt-base materials, the nickel-base/boride-type alloys possess moderate resistance to galling (Fig. 5). Of the nonferrous materials, the nickel-base/boride-type alloys are the least resistant to corrosion. This is attributed to the lack of chromium in the matrix that follows boride and carbide formation.

Originally, the nickel-base/boride-type alloys were developed from brazing alloy compositions specifically for use with the spray-and-fuse process (for which their self-fluxing properties are ideal). During the fusing cycle of this process, it is believed that oxides within the sprayed coating combine with some of the silicon and boron to form a borosilicate slag (which floats to the surface of the deposit). The only other commercially significant spray-and-fuse alloys are some silicon-containing and boron-containing derivatives of the cobalt-base/carbide-type materials. Microstructurally, and in a property sense, these alloys bear little resemblance to their traditional counterparts (because the presence of boron markedly changes the matrix chromium content and the types of hard phase that form during solidification.

Bronze Type. The two bronze compositions given in Table 5 fall in the aluminum bronze category. Silicon and other types of bronze are also available in welding consumable form for hardfacing. Aluminum, silicon, and iron are added to the bronzes to strengthen the solid solution, and, in excess of their solubility limits (about 8%, in the case of aluminum), to provide precipitation hardening.

The high resistance to sliding wear and cavitation erosion of these alloys is attributed to planar slip during deformation. This is believed to delay the onset and progression of microfatigue (as in the case of the cobalt-base alloys). Wear tests have shown that the aluminum bronzes possess anti-galling characteristics (self-coupled) comparable to those of ERCoCr-E; low-stress abrasion resistance of the aluminum bronzes, however, was very low.

Components typically protected using the aluminum bronzes include gears, cams, and cold drawing/forming dies. These alloys are not recommended for elevated-temperature use because their mechanical properties considerably decrease at temperatures >200 °C (>390 °F).

Friction and Wear of Cobalt-Base Wrought Alloys

Paul Crook, Haynes International, Inc.; Alan V. Levy, Lawrence Berkeley Laboratory

Introduction

COBALT-BASE WROUGHT ALLOYS can conveniently be categorized as follows:

- Alloys with high-carbon contents and designed for wear service
- Alloys designed for high-temperature service
- Alloys designed to combat simultaneous corrosion (aqueous) and wear

The high-carbon alloys, such as Alloy 6B and Alloy 6K, are essentially wrought versions of the weld overlay materials described in the article "Friction and Wear of Hardfacing Alloys" in this Volume. Wrought processing improves chemical homogeneity (important in a corrosion sense), markedly increases ductility, and modifies substantially the geometry of the carbide precipitates within the alloys (which in turn enhances resistance to low-stress abrasion). In terms of composition (Table 1), the alloys are essentially Co-Cr-W-C quaternaries with chromium providing strength and corrosion resistance to the solid solution in addition to functioning as the chief carbide former (during ally solidification). Tungsten provides additional solid solution strength. The attractive wear properties of these alloys are attributed chiefly to the unusual deformation characteristics imparted by cobalt. The carbides play a secondary role, being particularly important under conditions conducive to low-stress abrasion. With regard to the influence of cobalt, the low stacking fault energy of the (high-temperature stable) face-centered cubic (fcc) structure is important, as is the transformation to the (low-temperature stable) hexagonal close-packed (hcp) form under the action of mechanical stress (Ref 1, 2, 3, 4). The former is believed to delay fatigue crack initiation (a factor in many wear processes) through its influence on slip behavior and twinning propensity; the latter is believed to enhance fatigue life by reducing internal strain.

Table 1 Nominal compositions of wrought cobalt-base alloys

Alloy	Composition, wt%

MP35N	20	. . .	10	. . .	. . .	35	. . .	. . .	. . .	bal

The high-temperature alloys, such as Alloy 25 (L-605) and Alloy 188, are considerably more ductile, oxidation resistant, and microstructurally stable. Both examples contain approximately 0.1 wt% C (about one-tenth of that in Alloy 6B), which is sufficient to provide carbide strengthening, yet low enough to maintain ductility. Structural stability is enhanced in these alloys by nickel, which decreases the fcc/hcp transformation temperature in cobalt-base alloys (Ref 5). Intermetallic formation in Alloy 188 is minimized by control of the electron hole number (the intermetallic Laves phase is a common precipitate in the cobalt-base alloys during long-term exposure to elevated temperatures). Alloy 188 also contains a small amount of the rare-earth element lanthanum for increased resistance to oxidation (Table 1).

Materials in the third, and final, category differ from those already mentioned in that they utilize molybdenum in preference to tungsten. Whereas tungsten appears to be a more effective strengthener at a elevated temperatures, molybdenum appears to impart a greater degree of resistance to a variety of wet corrosive media. In addition, in some of these alloys--for example, MP35N alloy, MP159 alloy, and Ultimet alloy (1233)--carbon is held within the soluble range to improve resistance to heat-affected zone (HAZ) sensitization during welding.

Typical microstructures of the wrought cobalt-base alloys are shown in Fig. 1. All represent the alloys in the solution-annealed condition (their typical condition of use, except in the case of MP35N and MP159 alloys, which are controlled by cold reduction and aging and may be purchased at various strength levels).

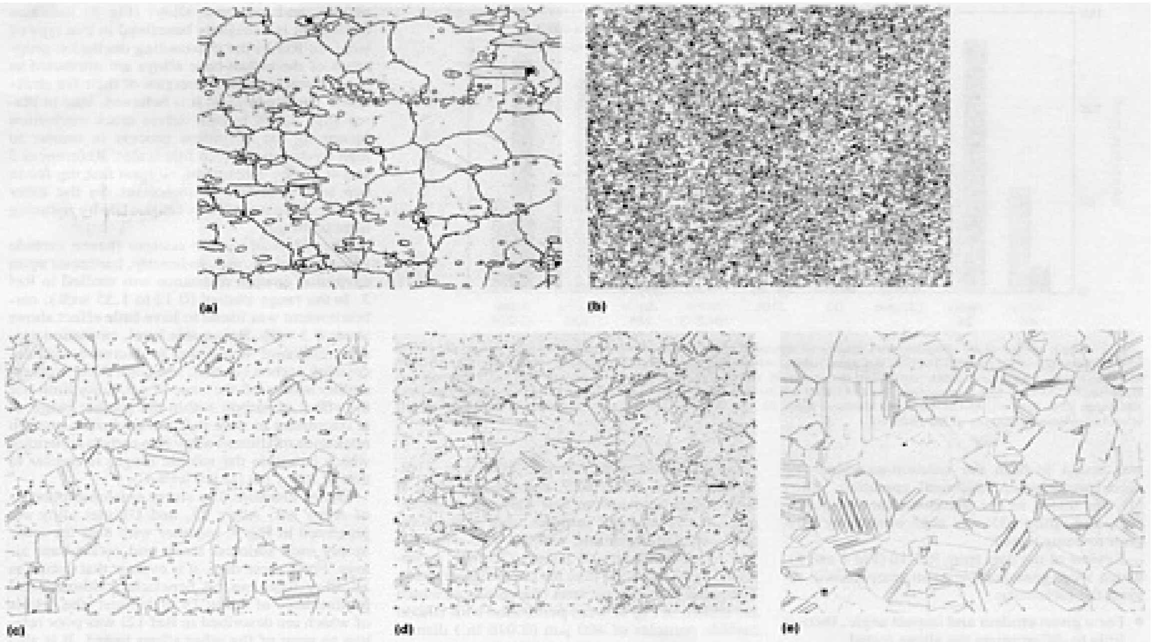

Fig. 1 Microstructure of wrought cobalt-base alloys etched with hydrochloric acid/oxalic acid solution. (a) Alloy 6B. (b) Alloy 6K. (c) Alloy 25. (d) Alloy 188. (e) Ultimet alloy. 200×

Alloy 6B (Fig. 1a) contains approximately 12.5 wt% carbides of the M_7C_3 and $M_{23}C_6$ types in the ratio 9:1 (Ref 3). Alloy 6K (Fig. 1b) exhibits an even greater carbide volume fraction, again with M_7C_3 as the predominant type (Ref 6). By virtue of much lower carbon contents, the high-temperature Alloy 25 (Fig. 1c) and Alloy 188 (Fig. 1d) contain appreciably less carbide precipitation. Nevertheless, this precipitation, which is predominantly of the M_6C type, is important to the high-temperature properties of these materials, partially because it restricts grain growth during heat treatment and service (Ref 7).

Ultimet alloy (Fig. 1e) is typical of the low-carbon corrosion-resistant alloys in that it exhibits no intragranular or grain boundary carbide precipitation, although a sparse dispersion of nitrides in evident in the structure.

In the solution-annealed condition, the wrought cobalt-base alloys exhibited a fcc matrix structure. With the exception of Alloy 188 (which is fcc stable), however, the alloys in Table 1 are metastable at room temperature and tend to transform to hexagonal close-packed under the action of mechanical stress or during heat treatment (at temperatures below the transformation temperature). Alloys 25, for example, is believed to be metastable at temperatures <760 °C (<1400 °F) (Ref 8).

Wear Properties

There are several distinct types of wear, and they generally fall into three main categories:

- Abrasive wear
- Erosive wear
- Sliding wear

Abrasive Wear

The low-stress and high-stress abrasive wear characteristics of three of the compositions in Table 1, relative to other common alloys, are shown in Fig. 2. Review of these (room temperature) data reveals:

- The importance of hard phases (carbides) within the microstructure, under conditions conducive to low-stress abrasion
- Their lack of importance under high-stress conditions (the performance of the carbide-containing Alloy 6B being similar to that of the carbide-free Ultimet alloy)

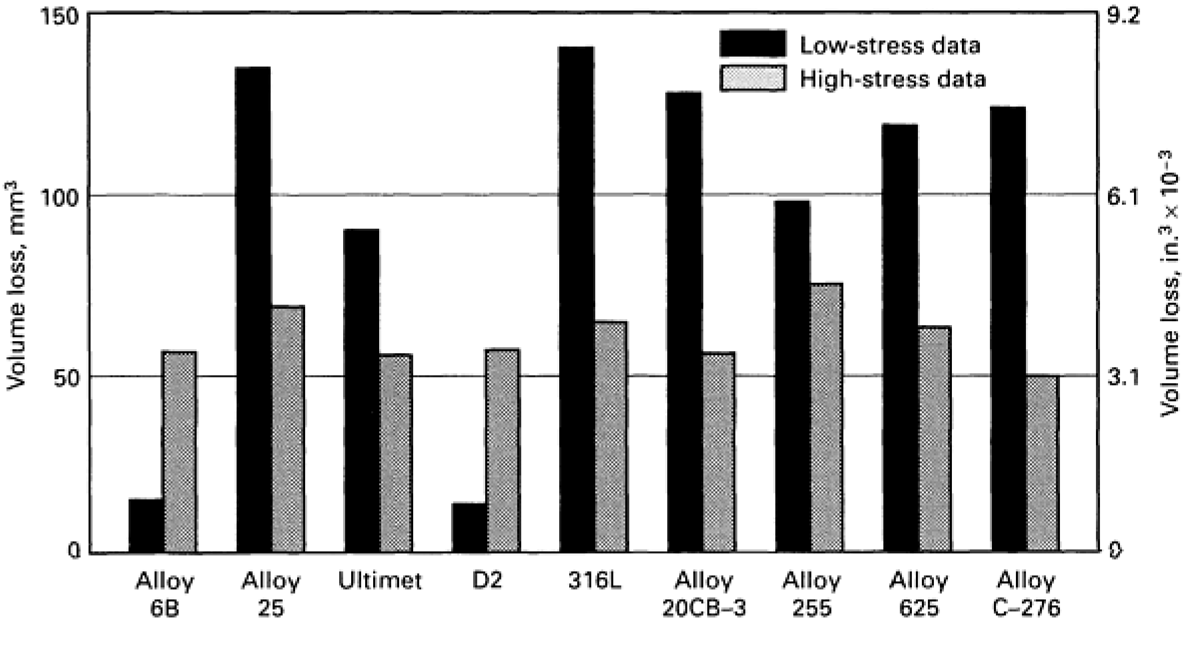

Fig. 2 Room-temperature abrasion test results of wrought cobalt-base alloys compared with other alloys. Solid

bars, low-stress data per ASTM G 65 dry sand/rubber wheel test (procedure B). Shaded bars, high-stress data per ASTM B 611 slurry/steel wheel test. Both tests used quartz sand of 212 to 300 μm (0.0085 to 0.012 in.) diameter as abrasive. ASTM G 65 test parameters: load, 13.6 kg (30 lb); wheel revolutions, 2000 rev at 200 rev/min; feed rate, 390 g/min (0.86 lb/min). ASTM B 611 parameters: load, 22.7 kg (50 lb); 1500 g (3.3 lb) sand to 940 g (2.1 lb) water; wheel revolutions, 250 rev at 245 rev/min

Low-Stress Abrasive Wear. The importance of the carbide precipitates, in particular their size and shape, under low-stress conditions can be appreciated by comparing the microstructures and volume losses for Alloy 6B and alloy 6 (the cast equivalent) in the article "Cobalt and Cobalt Alloys" in *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials,* Volume 2 of *ASM Handbook,* formerly 10th Edition, *Metals Handbook.* Large blocky carbides have been found to be of most benefit under such conditions (Ref 6).

The low-stress abrasion results for Alloys 25, Ultimet alloy, the stainless steels, and the high-nickel alloys correlate well with the annealed hardness of the samples (Table 2) with the exception of Alloy 25.

Table 2 Annealed hardnesses of low-stress abrasion samples of wrought cobalt-base alloys relative to other alloys

Alloy	Hardness, HRC
Alloy 6B	38.1
Alloy 25	24.7
Ultimet	35.6
D2 tool steel	59.5
316L stainless steel	81.6[(a)]
Alloy 20CB-3	86.8[(a)]
Alloy 255	27.2
Alloy 625	20.2
Alloy C-276	89.8[(a)]

(a) HRB

High-Stress Abrasive Wear. For the high-stress test, no relationship between room-temperature hardness and performance is evident. In fact, all the alloys, including Alloy 6B and D2 tool steel, fall within a narrow performance band, suggesting that resistance to fracture is at least as important as resistance to deformation under such conditions. It is noteworthy that the duplex (austenitic-ferritic) microstructure of Alloy 255 is beneficial under low-stress conditions, but detrimental in the high-stress case.

Erosive Wear

The cobalt-base wrought alloys have been evaluated under conditions conducive to three distinct forms of erosive wear:

- Solid-particle impingement erosion
- Cavitation erosion
- Slurry erosion

Solid-particle Impingement Erosion. To define the behavior of the cobalt-base wrought alloys under solid-particle impingement erosion conditions, the results of two independent studies (using the ASTM G 76 test apparatus shown in Fig. 3) are presented in graphical form in Fig. 4, 5, 6, and 7. In the first study by Ninham (Ref 10), Alloy 6B and Alloy 188 were compared with Alloy C-276, Alloy 255, and 718 at three impact angles (30, 60, and 90°) and for two types of erodent (silicon carbide particles of 250 to 300 μm, or 0.010 to 0.012 in., diameter and angular quartz particles of 70 to 200 μm, or 0.003 to 0.008 in., diameter). To assess the influence of alloy condition, Alloy 188 and Alloy C-276 were tested in both the solution annealed and 30% cold-worked conditions, and Alloy 718 was tested in both the solution-annealed and aged (precipitation-hardened) condition. Alloy 6B was tested in the solution-annealed condition, and Alloy 255 was cold worked by 30% prior to being tested.

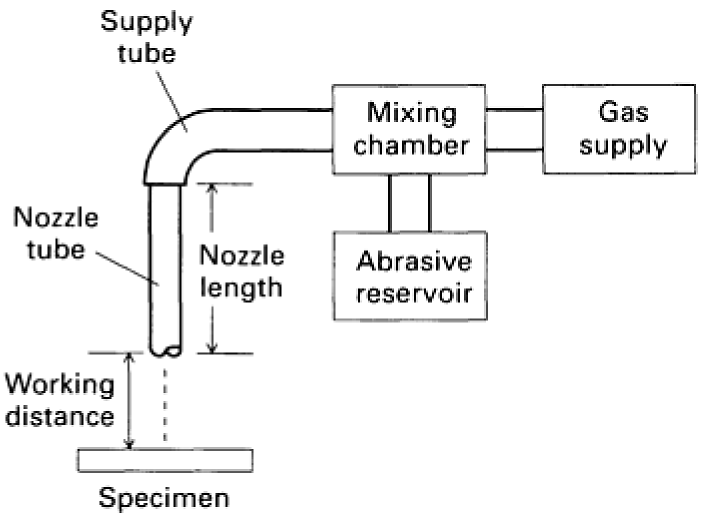

Fig. 3 Schematic showing key components of the ASTM G 76 solid-particle gas-jet impingement erosion test apparatus

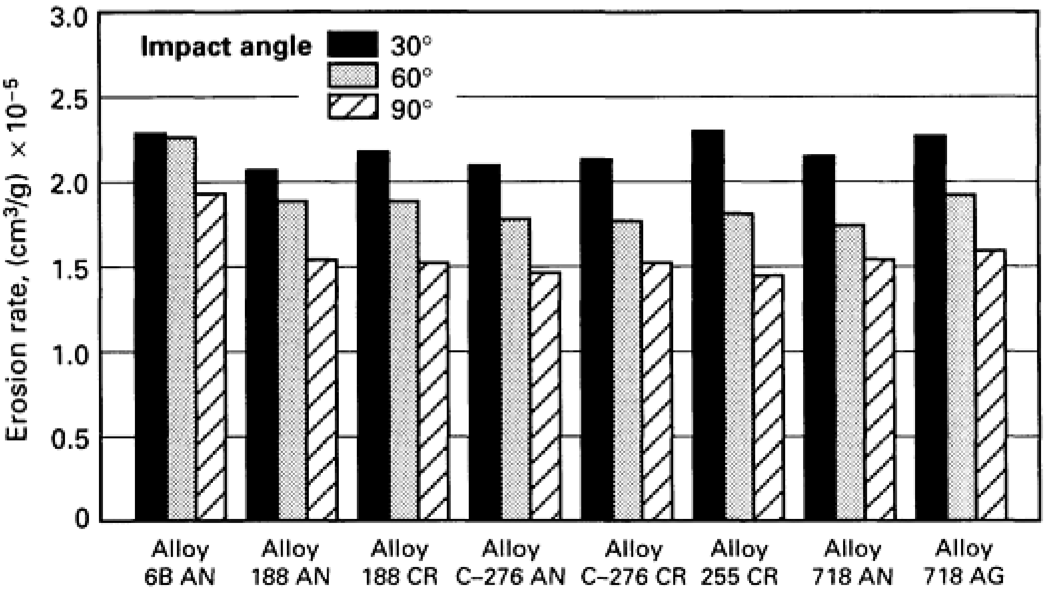

Fig. 4 Solid-particle impingement erosion test (ASTM G 76) results to compare cobalt-base alloys with selected alloys using a 250 to 300 μm (0.010 to 0.012 in.) diameter silicon carbide erodent at impact angles of 30, 60, and 90°. Tests conducted at room temperature with 60 m/s (200 ft/s) particle velocity. AN, annealed; CR, cold reduced; AG, aged. Source: Ref 10

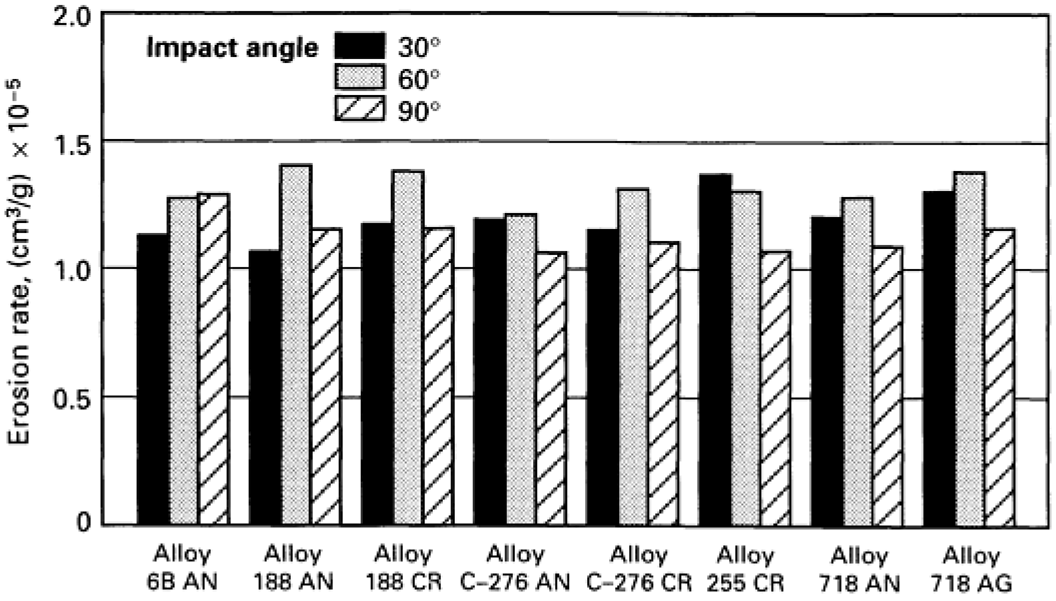

Fig. 5 Solid-particle impingement erosion test (ASTM G 76) results to compare cobalt-base alloys with selected alloys using a 75 to 200 μm (0.003 to 0.008 in.) diameter quartz erodent of impact angles of 30, 60, and 90°. Tests conducted at room temperature with 60 m/s (200 ft/s) particle velocity. AN, annealed; CR, cold reduced; AG, aged. Source: Ref 10

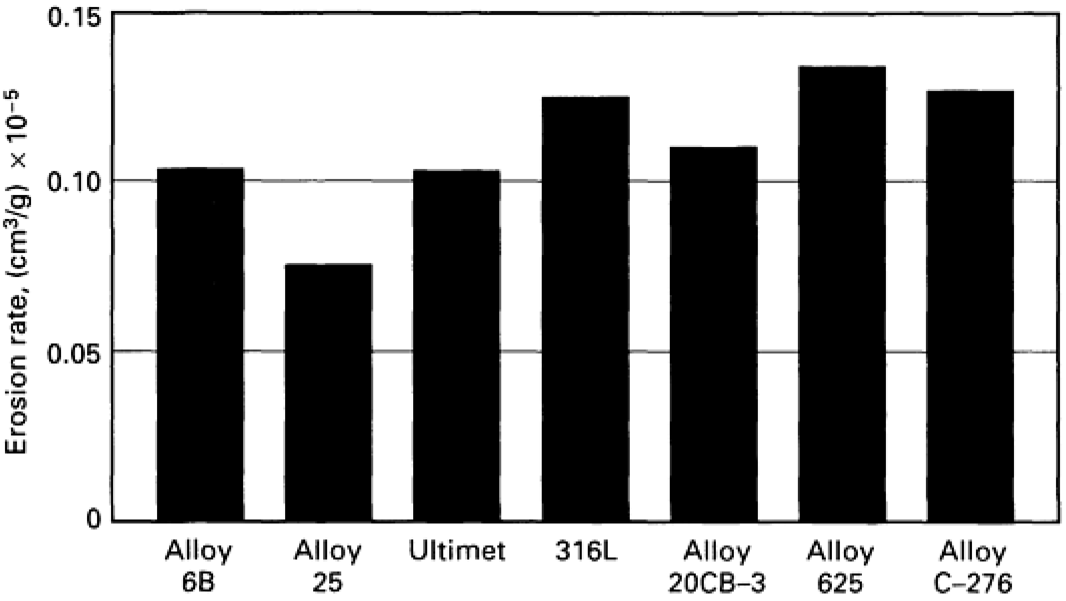

Fig. 6 Solid-particle impingement erosion test (ASTM G 76) results to compare cobalt-base alloys with selected alloys using a 400 μm (0.016 in.) mean diameter silicon carbide erodent at an impact angle of 60°. Tests parameters: test temperature, 20 °C (70 °F); particle velocity, 20 m/s (65 ft/s); particle feed rate, 0.02 g/s (4×10^{-5} lb/s)

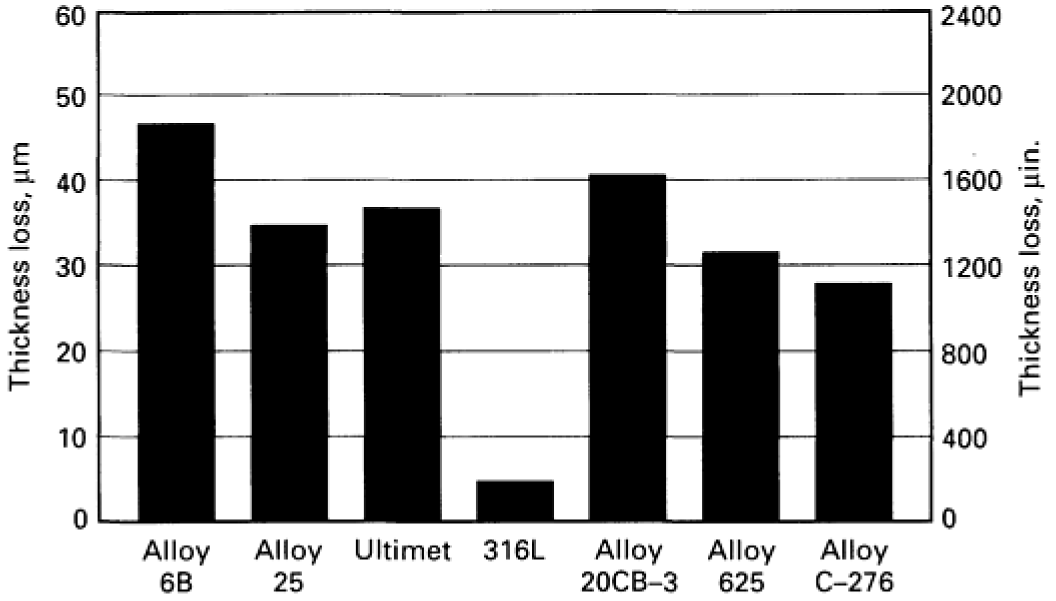

Fig. 7 Solid-particle impingement erosion test (ASTM G 76) results to compare cobalt-base alloys with selected alloys using an 80 μm (0.003 in.) mean diameter alumina erodent at an impact angle of 30°. Tests parameters: test temperature, 850 °C (1560 °F); particle velocity, 20 m/s (65 ft/s); particle feed rate, 0.02 g/s (4 × 10^{-5} lb/s)

Review of the data from Ref 10 (Fig. 4 and 5), which were generated at room temperature, reveals the following:

- For a given erodent and impact angle, there is little to differentiate the alloys tested
- Neither cold working nor precipitation hardening has a strong effect on solid-particle erosion resistance
- For silicon carbide, erosion rate decreases as impact angle increases, in the range 30 to 90°; this is consistent with other erosion studies of ductile materials (Ref 11)
- For quartz, this relationship does not apply because the materials tested have exhibited a maximum erosion rate at an impact angle of 60°; Alloy 6B is one of the two exceptions in this regard, having exhibited a maximum erosion rate at 90°

In the second solid-particle erosion study involving the cobalt-base wrought alloys by the authors, Alloy 6B, Alloy 25, and Ultimet alloy were compared with Alloy C-276, type 316L stainless, Alloy 625, and 20CB-3 alloy at both room temperature and elevated temperature. In this case, all samples were in the solution-annealed condition, and the tests were run at a particle velocity of 20 m/s (70 ft/s), as opposed to 60 m/s (200 ft/s) for the previous work. The room-temperature tests (the results of which are shown in Fig. 6) were performed with silicon carbide particles of 400 μm (0.016 in.) diameter, at an impact angle of 60°. The elevated-temperature (850 °C, or 1560 °F); tests were run with 80 μm (0.003 in.) diameter alumina particles at an impact angle of 30°; the results are shown in Fig. 7.

Under the conditions of the room-temperature test, the three cobalt-base alloys exhibited the lowest erosion rates. Alloy 25, in particular, was significantly more resistant to erosion than the other test alloys. At elevated temperature, however, 316L was by far the most erosion-resistant material, presumably due to the characteristics of the oxide scale during impingement.

Cavitation Erosion. Comparison of the cavitation erosion resistance of several cobalt-, nickel-, and iron-base alloys (Fig. 8) indicates that cobalt is extremely beneficial in this type of wear. In Ref 1, the outstanding cavitation properties of the cobalt-base alloys are attributed to the low stacking fault energies of their fcc structures. These energies, it is believed, lead to planar slip, which in turn delays crack nucleation (assuming the cavitation process is similar to high-cycle fatigue on a fine scale). References 3 and 4, on the other hand, suggest that the fcc to hcp transformation is important (in the latter case because it enhances fatigue life by reducing internal strain).

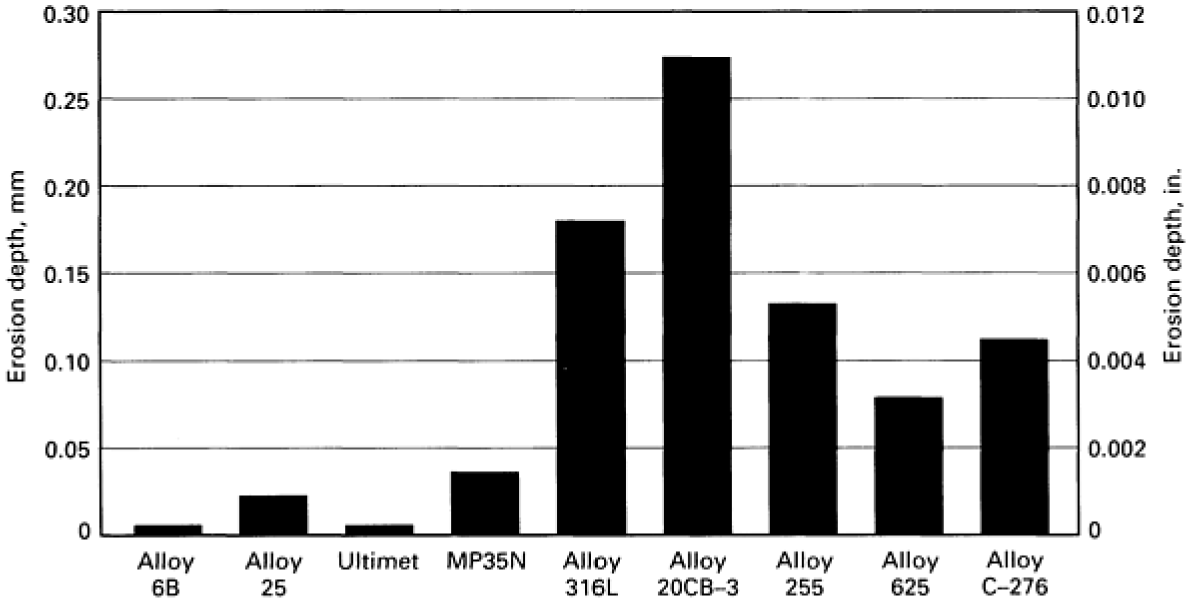

Fig. 8 Vibratory cavitation erosion test (ASTM G 32) results to relate cobalt-base wrought alloys with comparable alloys. Test parameters: test temperature, 16 °C (61 °F); test medium, distilled water; frequency, 20 kHz; amplitude, 0.05 mm (0.002 in.). All samples were solution annealed with the exception of MP35N alloy, which was tested in the work-strengthened condition.

The effect of carbon content (hence carbide volume fraction, and, indirectly, hardness) upon cavitation erosion resistance was studied in Ref 3. In the range studied (0.12 to 1.35 wt%), carbon content was found to have little effect above about 0.3 wt%. Below this level, cavitation erosion resistance was found to decrease with decreasing carbon content, although these workers neither addressed the issue of solubility limit nor the effect of carbon within the soluble range. It is interesting to note that the cavitation erosion resistance of Ultimet alloy (the carbon content of which is within the soluble range) is similar to that of Alloy 6B (at 1.0 wt% C).

Slurry Erosion. The slurry erosion properties of Alloy 6B, Alloy 25, and Ultimet alloy are presented in Fig. 9, together with data for commonly used stainless steels and nickel-base alloys. From these data, it is evident that cobalt as an alloy base can be beneficial, although the performance of Alloy 25 in this test (the details of which are described in Ref 12) was poor relative to most of the other alloys tested. It is also evident that carbide precipitates within the microstructure may be beneficial (comparing the erosion depths for Alloy 6B and Ultimet alloy).

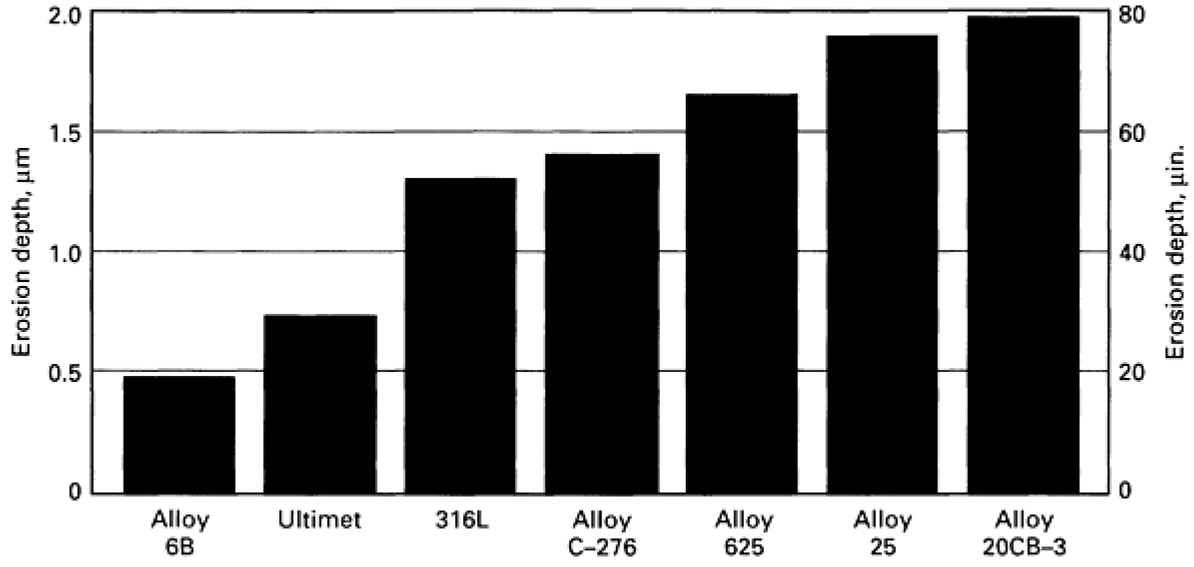

Fig. 9 Slurry erosion pot test data to relate cobalt-base wrought alloys with comparable alloys. Test parameters: test temperature, 20 °C (70 °F); test medium, 80 μm (0.003 in.) mean diameter alumina in tap water; particle loading, 0.12 kg/L; particle velocity, 5 m/s (16 ft/s); impact angle, 30°

These results are somewhat consistent with previous slurry erosion test data (Ref 13) on cobalt-base hardfacing alloys, albeit in a sand/water slurry, as opposed to the alumina/water medium used to generate the values in Fig. 9. In the previous work, a wide spectrum of engineering materials was tested, and, of these, Alloy 6 (the cast counterpart of Alloy 6B) was among the most resistant, wearing at only 5.5% of the rate of carbon steel. The results in Ref 13 indicated that the cast cobalt-base alloys of higher carbon content (and higher hardness) were much less resistant to slurry erosion, suggesting that the relationship between carbide volume fraction and slurry erosion resistance is far from linear for the cobalt-base alloys.

Sliding Wear

Of the three major types of wear, sliding is perhaps the most complex, not in concept, but in the way different materials respond to sliding conditions. Sliding wear is a possibility whenever two surfaces are forced together and moved relative to one another. The chances of damage are markedly increased if the two surfaces are metallic in nature, and if there is little or no lubrication present.

Galling. The outstanding resistance of the cobalt-base wrought alloys to galling, under self-mated conditions, is apparent from the pin-block test data presented in Fig. 10. Unfortunately, the test conditions (ten strokes through an arc of 120°) were too severe for the standard (austenitic and ferritic/austenitic) stainless steels. Even Nitronic 60, a type 200 stainless steel known for its resistance to galling, exhibited considerable damage (change in surface roughness) at the test load employed.

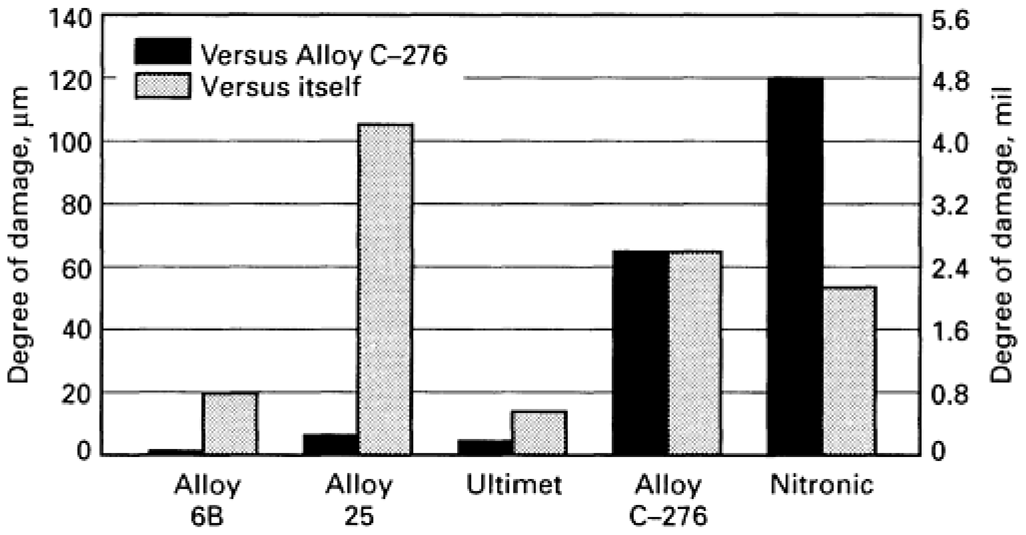

Fig. 10 Comparison of galling test data for cobalt-base wrought alloys with other selected alloys. Pin-on-block test parameters: test temperature, 20 °C (70 °F); number of strokes, 10 strokes through 120° arc; 2722 kg (6000 lb)

As may be deduced from Fig. 10, the coupling of dissimilar materials in a sliding system complicates the issue of wear performance, possibly because the interfacial bonding characteristics are difficult to predict. Nickel in Ultimet alloy, for example, is detrimental under self-mated conditions, but beneficial when sliding against alloy C-276 (Fig. 11).

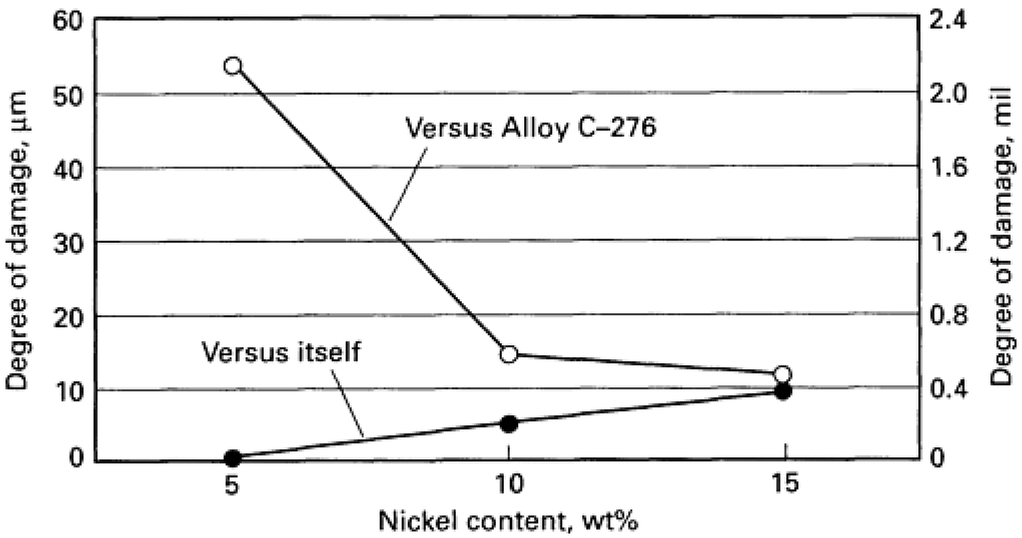

Fig. 11 Effect of nickel content on the antigalling properties of Ultimet alloy. Pin-on-block test parameters; test temperature, 20 °C (70 °F); number of strokes, 10 strokes through 120° arc; load, 2722 kg (6000 lb)

Oxide Control. Although elevated-temperature sliding wear data for the cobalt-base wrought alloys are not available, work with cobalt-base castings and weld overlays (Ref 14, 15) indicates that maximum wear rates occur at around 250 °C (480 °F) under a variety of sliding conditions and that above this temperature, oxide control of the sliding wear process is prevalent. Both Ref 14 and 15 discuss the advantages of cobalt as an alloy base over nickel (relative to sliding wear at low temperatures.)

The unlubricated dynamic coefficient of friction was found to vary with time in both of these studies. In Ref 14, the coefficient was found to vary between 0.4 and 1.4 for alloy 31 (self-mated) at room temperature (the value increasing with test time). At high temperatures, friction coefficient values appear to be more stable, a short, running-in period. At 800 °C (1470 °F), for example, Alloy 31 (self-mated) exhibited a value of between 0.3 and 0.4 after 15 min, up to completion of the test at 67 h.

Mechanical Properties

The mechanical properties of the cobalt-base wrought alloys are summarized in Vol 2 of the *ASM Handbook* (1990). Because they may be of some relevance to hot abrasion (low stress), recently generated hot hardness values are presented in Table 3 for Alloy 6B, Alloy 25, Alloy 188, and Ultimet alloy. It is significant that, despite the considerable spread in their room temperature hardness values, these alloys possess nearly equal resistance to deformation at 871 °C (1600 °F) and 982 °C (1800 °F).

Table 3 Hot hardnesses of cobalt-base wrought alloys

Temperature		Hardness for indicated alloy, DPH[(a)]			
°C	°F	Alloy 6B	Alloy 25	Alloy 188	Ultimet
RT[(b)]	RT[(b)]	374	285	248	296

Wear-Related Applications

As may be deduced from the wear data presented in this article, the cobalt-base alloys provide high resistance to sliding wear, slurry erosion, and cavitation erosion (relative to the stainless steels, nickel-base superalloys, and high-nickel corrosion alloys). Alloy 6B and Alloy 6K also possess outstanding resistance to low-stress abrasion. Industrial applications of the alloys tend to reflect these general properties and their resistance to corrosion and high-temperature strength.

The alloys are used for sliding wear applications such as valves, both in the chemical processing industries and in the power industries (largely for steam control). Furthermore, Alloy 25 is used as a bearing material, and Alloy 6B is widely used to protect the nose sections of industrial chain saws. Ultimet alloy has been used for electrogalvanizing rolls, where both corrosion and sliding wear resistance are required.

The erosion properties of the cobalt-base alloys have led to their use in nozzles, valves (subjected to cavitation damage or slurries), pumps, and mixing blades. Alloy 6B is also used to protect steam turbine blades from liquid droplet erosion (it appears that the advantages of cobalt as an alloy base extend to this form of erosion also).

From an abrasion standpoint, notable applications of Alloy 6B and Alloy 6K include scraper knives and blades (for the chemical and food processing industries) and knives for the textile industries.

Friction and Wear of Ordered Intermetallic Alloys of Ni_3Al

Peter J. Blau, Metals and Ceramics Division, Oak Ridge National Laboratory

Introduction

ALLOYS based on the ordered intermetallic compound Ni_3Al are a relatively new development; however, the compound has long been alternatively known as the γ' phase in superalloys. Owing to the alloys' relatively recent introduction, most of the information available on the tribological properties of these alloys has been derived from laboratory tests and not from engineering applications. However, a number of laboratory studies have indicated that nickel aluminide alloys have significant potential in wear-critical applications, especially in cavitation erosion and in sliding wear at temperatures between ~400 and 650 °C (~750 and 1200 °F). In this article, the compositions, physical properties, mechanical properties, and limited friction and wear data for several of the leading compositions of nickel aluminide alloys are provided. The wear data include cavitation wear, solid-particle erosive wear, abrasive wear, and sliding wear.

Composition and Structure of Nickel Aluminide Alloys

Commercial versions of nickel aluminide alloys have recently been developed. In the United States, Oak Ridge National Laboratory (ORNL) has been a major developer; consequently, its numbering system has been adopted for use in this article. Unless otherwise cited, property data were obtained from the Metals and Ceramics Division of ORNL (Ref 1). The compositions of several nickel aluminide alloys are given in Table 1. A more detailed discussion of the structure and properties of ordered intermetallic alloys, including nickel aluminide alloys, is given by Liu *et al.* in the article "Ordered Intermetallics" in *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials,* Volume 2 of the *ASM Handbook,* formerly 10th Edition *Metals Handbook* (Ref 2).

(a) Designations used by Oak Ridge National Laboratory, Oak Ridge, TN

During the later part of the 1970s, it was found that small boron additions were critical for achieving reasonable levels of ductility in the alloys. Boron is thought to increase grain boundary cohesiveness, thereby reducing the tenacity for brittle intergranular fracture. Other alloying additions were made to improve strength, castability, hot workability, and corrosion resistance.

Ordered nickel aluminide (Ni_3Al) alloys are based on an $L1_2$ crystal structure. The unit cell consists of a face-centered cubic (fcc) arrangement in which the aluminum atoms occupy the corner positions and the nickel atoms preferentially occupy the face-centered positions. The fact that atoms occupy preferred positions in the crystal structure imparts unusual mechanical properties to the nickel aluminide alloys. These properties will be described in the section "Mechanical Properties" in this article. The presence of superdislocations, their dissociation into partials, and their associated mechanisms of cross-slip affect the temperature versus strength behavior of Ni_3Al alloys.

Nickel aluminide alloys are still under development and commercial evaluation. It is likely that new compositions will become available. However, the commercialization of the alloys will be strongly driven by the price of nickel and by the presence of specific applications for which nickel aluminide alloys may be the only performance-based choice.

Physical Properties

Little data exist on the physical properties of the whole series of nickel aluminide alloys; however, the information in Table 2 summarizes the effect of small changes in stoichiometry of Ni_3Al on several physical properties of the material (Ref 3). Data showing the effect of temperature on electrical resistivity, thermal conductivity, and the mean coefficient of thermal expansion are also given in Table 2.

Table 2 Physical properties of selected nickel-aluminum binary alloys

Data are for arc-melted, homogenized, and annealed specimens produced from high-purity nickel and aluminum stock.

Mechanical Properties

Among the most striking properties of nickel aluminide alloys, and that which captured initial interest among metal producers, is their rising yield strength with rising temperature. Figure 1 shows that the yield strength of four nickel aluminide alloys tends to rise to a maximum in the temperature range of ~400 to 650 °C (~750 to 1200 °F). Above this temperature range, the yield strength declines. The effect of cold working on the yield strength of IC-50 alloy is shown in Fig. 2. Up to test temperatures of ~600 °C (~1110 °F), cold working had an effect on the yield strength, but at a test temperature of 800 °C (1470 °F), there was no significant enhancement of yield strength.

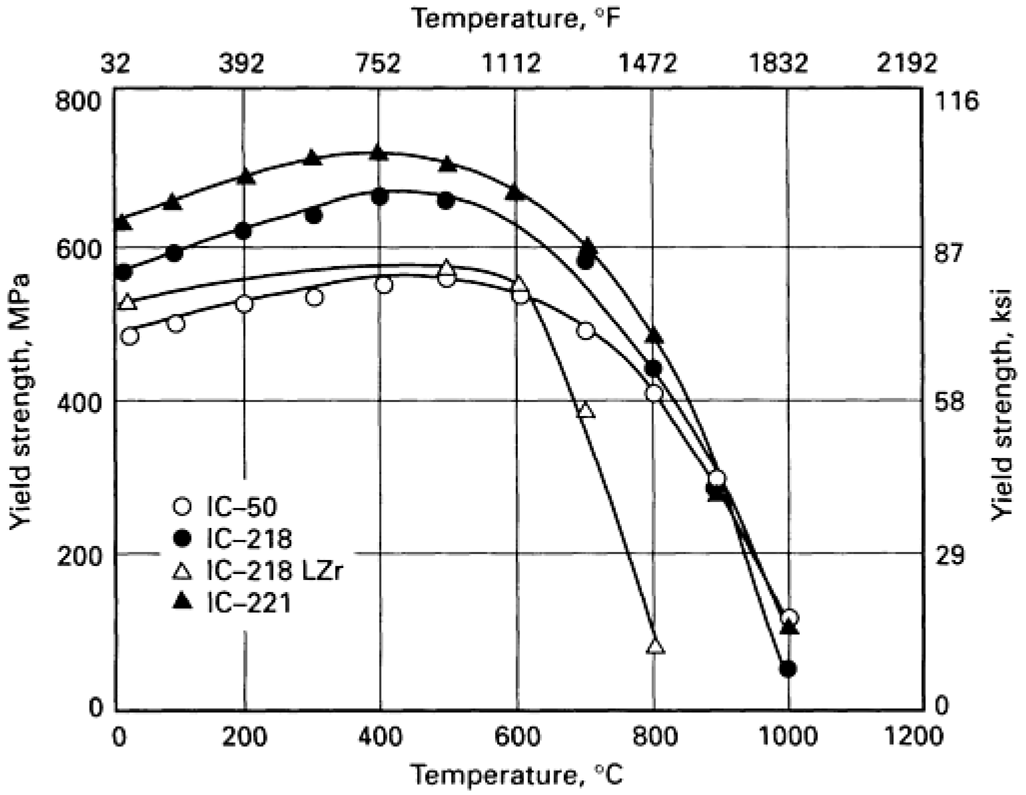

Fig. 1 Variation of yield strength with test temperature for selected nickel aluminide alloys. Strain rate, 0.5 mm/mm/min

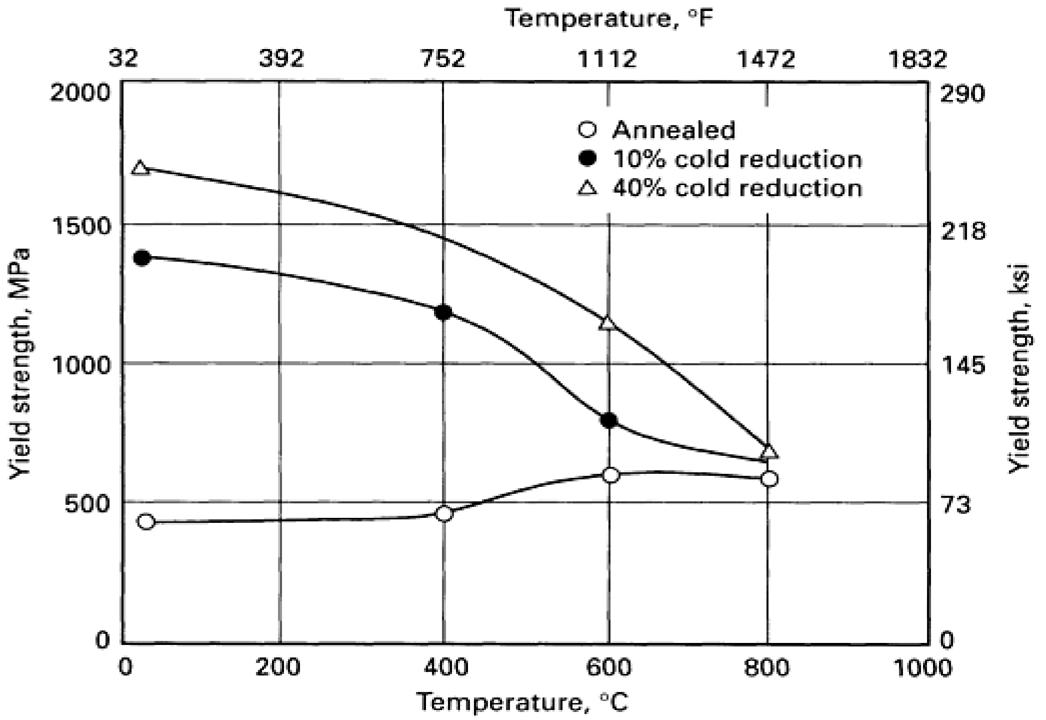

Fig. 2 Plot of yield strength versus test temperature of IC-50 nickel aluminide alloy as a function of cold working

The elastic (Young's) modulus of four nickel aluminide alloys is given in Table 3. Data on the effects of temperature on the elastic modulus of three of the alloys are also provided.

As with most metal alloys, the manner of fabrication and treatment affects the hardness of nickel aluminide alloys. Knoop microindentation hardness data for six nickel aluminide alloys in different forms are given in Table 4. All table data were obtained with a 100 gf (0.981 N) load. As indicated by IC-50 data in Table 4, the hardness of the alloy was observed to vary by as much as a factor of 1.7 from one form to another. Knoop microindentation hardness numbers well above 6.0 GPa (612 kg/mm^2) have been recorded on cross sections of heavily deformed machining chips of nickel aluminide alloy IC-218 LZr (Ref 4). Similar values are observed in the highly deformed, subsurface layers produced by unlubricated sliding contact of this alloy with tungsten carbide at room temperature (RT). The microindentation hardnesses of several of the counterface materials--used in the sliding experiments to be discussed in the section "Sliding Friction and Wear Data" in this article--are also given in Table 4.

Table 4 Knoop microindentation hardness of nickel aluminide alloys and selected slider experiment counterface materials

Nickel Aluminide Wear Data

Nickel aluminide wear data, as presented here, fall into three main categories:

- Erosive wear (which includes cavitation erosion and solid-particle erosion

- Abrasive wear
- Sliding wear

Cavitation Erosion

A study of the cavitation erosion behavior of several nickel aluminide alloys in pressurized water was conducted at the Norris Engineering Laboratory of the Tennessee Valley Authority using a specially designed cavitating jet apparatus (Ref 5, 6). High-pressure water was supplied by a positive-displacement pump (rated for a flow of 0.19 L/s, or 3.0 gal/min, at 69.0 MPa, or 10 ksi) to an adjustable nozzle. Data for a number of alloys applied to test specimen surfaces or as bulk specimens subjected to 41.6 MPa (6 ksi) operating pressure are given in Table 5. The data in Table 5 show that, of all the materials tested, three nickel aluminide alloys were the most resistant to cavitation erosion.

Table 5 Comparison of jet cavitation erosion data for three nickel aluminide alloys and other selected alloys relative to cold-rolled carbon steel

Operating pressure was 40 MPa (6 ksi).

Alloy	Cavitation erosion rate	
	Weight loss, mg/h	**Relative rate**
Carbon steel (cold-rolled bar)	32.3	1.0
Type 304 stainless steel plate	33.2	1.1
Type 308 stainless steel overlay (stick weld)	31.6	1.0
Nitronic 60 bar stock	12.8	0.4
Stellite 21 (stick)	7.3	0.2
IC-50 nickel aluminide (plasma weld overlay)	7.0	0.2
Stoody Deloro HGl (4 mm, or $\frac{5}{32}$ in., stick)	6.1	0.2
IC-50 as-formed	4.1	0.1
IC-218 nickel aluminide	2.9	0.09
IC-221 nickel aluminide	2.5	0.08
IC-50 nickel aluminide (cold worked)	1.4	0.04

Source: Ref 7

Solid-Particle Erosion

Sahoo *et al.* (Ref 8) conducted a study of the solid-particle erosion resistance of nickel aluminide alloys IC-50 and IC-218, in both annealed and cold-rolled conditions, compared with type 304H stainless steel. The alloys were cut into 25 × 30 mm (0.98 × 1.2 in.) coupons and finished with 600-grit abrasive prior to testing. Silicon carbide grains averaging 180 μm (0.0072 in.) diameter were used as the erodent at a measured nozzle velocity of 25 m/s (82 ft/s) and fed into the preheated gas stream at 10g/min (0.22 lb/min). The sample chamber was also heated. A carousel-type specimen holder permitted up to four specimens to be tested sequentially. After being exposed to 100 g (0.2 lb) of erodent, the specimens were each weighed to determine the erosion rate. Table 6 shows the effects of carrier gas, temperature, impingement angle, and alloy condition on the erosion rate. For nickel aluminide alloys that were eroded at 600 °C (1110 °F), there was a slight reduction in the erosion rate for the air atmosphere compared to the nitrogen atmosphere in the case of the cold-rolled samples. The particle impingement angle did have a marked effect on the erosion rate. As is characteristic of metals, the 30° impact angle gave higher rates than the 90° impact angle. Temperature of erosion had very little effect on the erosion rates of nickel aluminide, although it appeared to slightly increase the low-angle erosion rate of the steel and decrease the normal incidence erosion rate of the steel. Overall, there was not much difference in the erosion rates of nickel aluminide alloys when compared to type 304H stainless steel under the same conditions. As with the cavitation experiments discussed previously in the section "Cavitation Erosion" in this article, these tests represent only a small number of conditions, and the erosion behavior of nickel aluminide alloys may vary considerably from the present results under other conditions.

Table 6 Solid-particle erosion data for IC-50 and IC-218 twin-roll cast nickel aluminide alloys relative to type 304H stainless steel when using silicon carbide as the erodent

Test conditions[a]				Erosion rate as a function of indicated alloy and alloy processing[b]				
Carrier gas	Gas stream temperature		Impingement angle	IC-50		IC-218		Type 304H stainless steel
	°C	°F		Annealed	Cold rolled	Annealed	Cold rolled	
Nitrogen	25	75	30°	4.0	4.2	4.0	4.3	3.7
			90°	2.4	2.2	2.4	2.5	2.8
	600	1110	30°	3.8	4.3	3.9	4.3	4.2
			90°	2.3	2.5	2.2	2.6	2.2
Air	600	1110	30°	3.8	4.0	3.8	3.9	4.2

(a) Test parameters: particle size, 180 μm (0.0072 in.) diameter; gas stream flow, 10 g/min (0.02 lb/min); nozzle velocity, 25 m/s (82 ft/s).

(b) Erosion rate is figured as (grams material loss/100 g erodent) × 10^{-4}.

Abrasive Wear

Two recent studies have involved the abrasive wear behavior of nickel aluminide alloys (Ref 6, 9). Marquardt and Wert (Ref 9) used 400-grit silicon carbide abrasive paper affixed to a rotating flat disk to test the two-body abrasion behavior of annealed IC-15 (12.7 wt% Al, 0.05 wt% B, and 87.3 wt% Ni) pin specimens. The sliding alloy pin was precessed during the experiment such that new abrasive was continuously exposed to the slider. Each test at the stated normal force was repeated three times for a total sliding distance of 90 m (300 ft). A summary of the results is given in Table 7. These results indicate that under the stated conditions, IC-15 was slightly worse in abrasion resistance than type 316 stainless steel, a material not generally recommended for abrasive wear conditions.

Table 7 Two-body abrasive wear data for IC-15 nickel aluminide alloy relative to selected steel alloys

Normal force		Abrasive wear rates for indicated alloy, mg/m			
N	kgf	52100 bearing steel	Type 304L stainless steel	Type 316 stainless steel	IC-15
1.96	0.196	0.127	0.171	0.171	0.190
4.91	0.491	0.297	0.434	0.387	0.482

Source: Ref 9

Johnson *et al.* (Ref 6) studied the three-body abrasive wear of three nickel aluminide alloys: IC-50, IC-218, and IC-221. They used the ASTM standard test method G 65, which involves sliding of test coupons against a moving stream of sand particles held against the specimen by a rotating rubber-faced wheel. The parameters used include 50 N (5 kgf) load, wheel diameter of 229 mm (9.02 in.) rotation at 230 rev/min, 60-mesh dry sand flow rate of 4.2 cm^3/s (0.26 $in.^3/s$) and a test duration of 540 s. Of the three alloys tested, IC-50 (the basic Ni-Al-B composition) exhibited the best abrasion resistance.

Sliding Friction and Wear Data

Only limited laboratory data on the sliding friction and wear data is available for nickel aluminide alloys. Investigations were done at Vanderbilt University (Ref 9), The Ohio State University (Ref 10), and at Oak Ridge National Laboratory (Ref 11, 12, 13). Marquardt and Wert (Ref 9) compared the sliding wear of IC-15 with 52100 bearing steel, type 304L stainless steel, and type 316 stainless steel in self-mated, pin-on-disk sliding wear tests at room temperature. Relative to the wear rate of the 52100 steel pin, which wore the least, the wear rates of the other materials were: type 316 stainless steel, 19.3; type 304L stainless steel, 27.3; and IC-15, 38.3. Therefore, the nickel aluminide alloy experienced the worst wear of all four materials at room temperature.

Bonda and Rigney (Ref 10) investigated the sliding wear of Ni_3Al with and without boron and IC-218 in both air and vacuum (1 mPa, or 0.15 × 10^{-6} psi) at room temperature and at 400 °C (750 °F). The basic alloys were produced by thermal spraying and the IC-218 was produced by hot extrusion of the alloy powder. The test geometry was the edge of a small disk slidingon the surface of a larger, vertically oriented disk. The vertical disk orientation was used so that debris could be collected below the contact. Materials were slid against themselves. Normal load was 14.7 N (1.5 kgf), and sliding speeds were 15 to 19 mm/s (0.59 to 0.75 in./s). Sliding was smoother in air than in vacuum for all materials at room temperature, but the wear rates were much higher in air. The effect of temperature was found to be small in a vacuum, but large in air, suggesting the importance of oxygen in the wear process. The wear behavior of the basic alloy was not affected by the presence of boron under all testing conditions. In air and at both room temperature and 400 °C (750 °F), the disks of IC-218 alloy wore the most of all three materials.

The remainder of the friction and wear test data presented here where obtained at Oak Ridge National Laboratory. Two types of sliding experiments are described:

- Unidirectional pin-on-disk experiments
- Reciprocating-sphere or cylinder-on flat experiments

Unidirectional, Unlubricated Sliding Results. Unidirectional sliding friction and wear data were obtained using the equipment illustrated in Fig. 3 and 4. In all experiments, the pin specimen was a 9.53 mm ($\frac{3}{8}$ in.) diameter ball of the specified material held fixed in the holder. The natural frequency of the apparatus under load was about 20 Hz. All tests were conducted in air at typical relative humidity levels ranging from 40 to 70%. The pin was deadweight loaded to provide the reported normal forces. The sliding velocity was 0.1 m/s (0.3 ft/s) except where otherwise specified. Test duration was either 10,000 disk revolutions or 1 km (3000 ft) sliding distance. In the current case and considering the range of wear track radii involved in these experiments, these durations are approximately the same (±15%). Disk specimens were metallographically polished and cleaned in acetone and methanol before testing. Spheres were also solvent cleaned before testing. Friction values reported are the nominal values obtained after running-in transients had subsided.

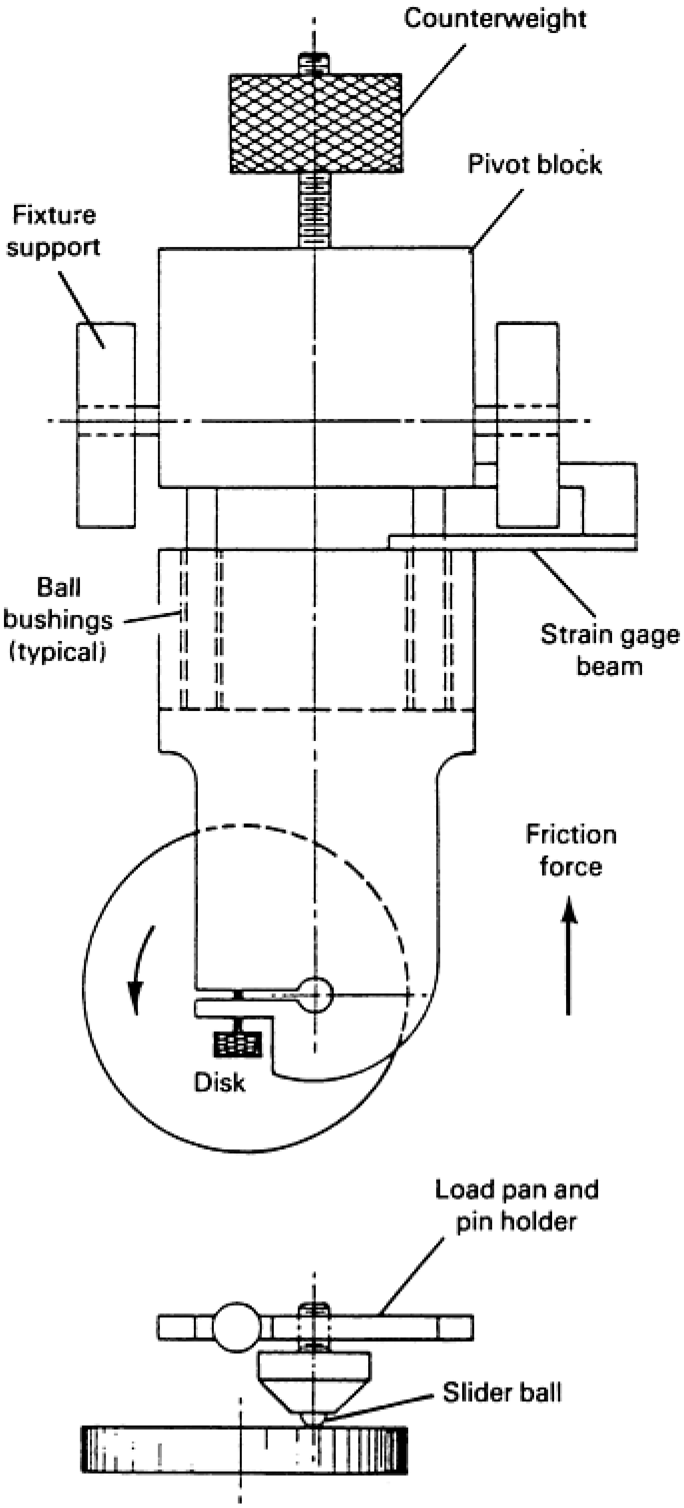

Fig. 3 Pin-on-disk test apparatus used to obtain unidirectional sliding friction and wear data in air at room temperature

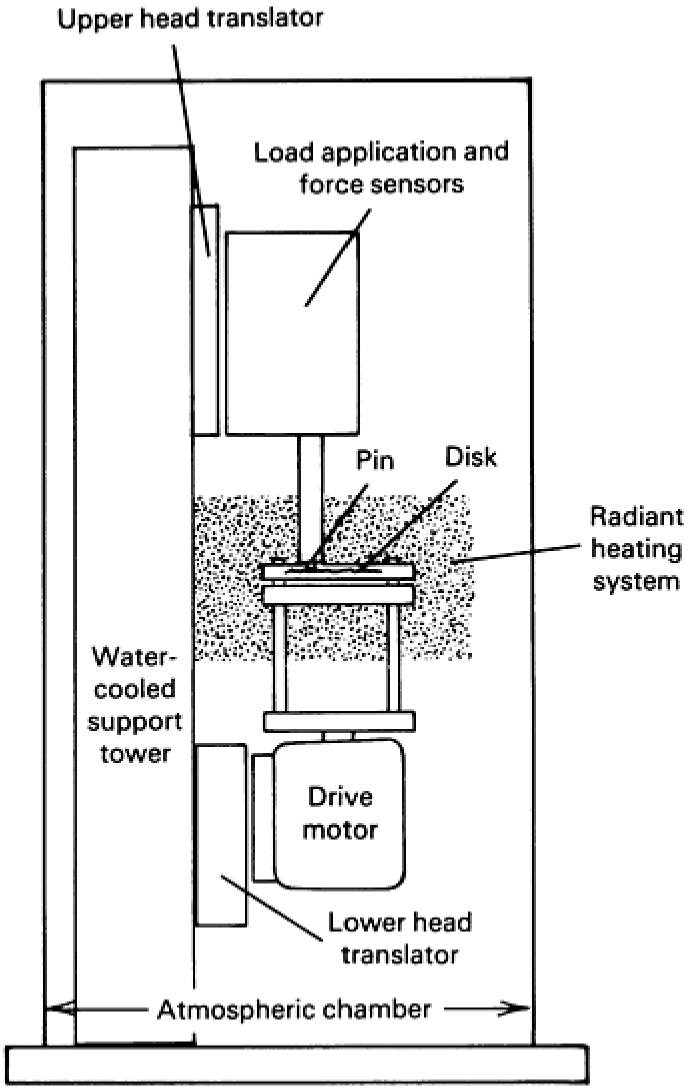

Fig. 4 Pin-on-disk test device used to measure unidirectional sliding friction and wear in a vacuum at both room temperature and elevated temperatures

Wear rates of the pin specimens were obtained by photographing each wear scar, measuring its diameter, and computing the volume removed based on the assumption of a flat-based, spherical cap. Wear rates of the flat, disk specimens were obtained from stylus tracings across the wear tracks at at least three locations and then by multiplying the average, digitized cross-sectional area of the track by the track length (computed from the diameter of the track measured at its center). All wear rates have been expressed in the traditional "wear factor" notation of volume lost normalized by the total sliding distance and by the applied load (that is, $mm^3/N \cdot m$). It is recognized that the contact by the pin tip is approximately continuous and that the contact by any point on the disk track is intermittent. Therefore, normalizing the disk wear volume by the total sliding distance experienced by the pin is fundamentally incorrect. However, a great quantity of historical pin-on-disk results have been reported on this basis, and in order to compare the current results with these values, the former method of wear volume normalization was retained.

Pin-on-disk friction and wear data for five nickel aluminide alloys against several metals and ceramics (tested both at room temperature and at elevated at temperatures) are given in Table 8. The friction coefficients ad wear rates of the various nickel aluminide combinations at room temperature are very similar to those steel on steel and do not represent any significant tribological advantages in this area. Studies of combined wear and corrosion of these alloys have yet to be done.

Table 8 Pin-on-disk friction and wear data for several nickel aluminide alloys tested in air at selected temperatures with 10 N (1 kgf) load

Disk alloy	Test temperature		Slider ball material[a]	Nozzle velocity		Friction coefficient[b]	Wear factor[c] (mm^3/N · m) × 10^{-7}

(e) Load, 0.98 N.

(f) Not measurable due to material adhering to the pin tip

The friction coefficients of the sliding couples were not substantially better at high temperature than the values obtained at room temperature; however, the high-temperature wear rates of the IC-218 LZr against tungsten carbide and the IC-74M against alumina (Fig. 5) were much better than those at room temperature. This behavior and the results from the referenced studies suggest that the nickel aluminide alloys have the potential to serve as sliding partners for ceramics in the temperature range of 400 to 650 °C (750 to 1200 °F). More work on modifying the thermomechanical processing of nickel aluminide alloys for peak wear resistance is needed to maximize the improved wear resistance that these alloys have shown at elevated temperatures.

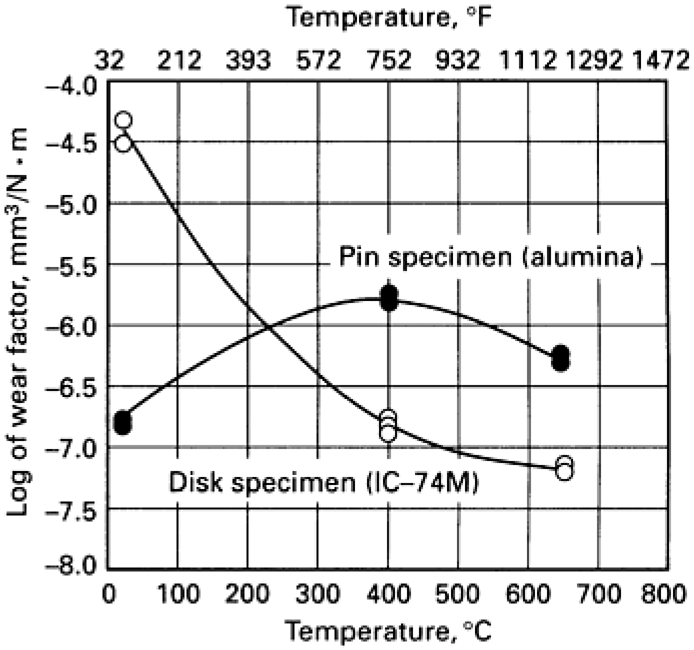

Fig. 5 Wear data for IC-74M disk against alumina pin in air at selected temperatures (room temperature; 400 °C, or 750 °F; and 650 °C, or 1200 °F). Pin-on-disk apparatus parameters: load, 1.0 N (0.1 kgf); sliding speed, 0.1 m/s (0.3 ft/s); wheel travel, 10,000 rotations

Reciprocating Sliding Friction and Wear Tests. Reciprocating (back-and-forth) testing of various combinations of nickel aluminide alloys with other materials were conducted on a commercially manufactured Cameron-Plint TE-77 high-frequently machine. As with the unidirectional tests, the slider was a 9.53 mm (0.375 in.) diameter ball clamped in the device. The frequency of oscillation was set at 10.0 Hz, the stroke length was 10.0 mm (0.394 in.), and the normal load was 25.0 N (2.55 kgf). Both unlubricated and lubricated tests were performed in room-temperature air. The duration of the test was 600 s (120 m, or 390 ft, sliding distance). Wear volume for the slider specimens was determined in the manner used for unidirectional tests described in the section "Unidirectional, Unlubricated Sliding Results" in this article. Flat-specimen wear volumes were obtained by three stylus traces across each scar, but the wear factor for the flat specimen was reported in terms of $mm^3/N \cdot cycle$ instead of $mm^3/N \cdot m$ to account for the fatigue aspects of this type of test.

Table 9 lists the unlubricated friction and wear data for two nickel aluminide alloys sliding against three different materials at room temperature at an average velocity of 0.2 m/s (0.7 ft/s). The bearing steel/nickel aluminide combination produced the most wear in both alloys, and the silicon nitride/nickel aluminide combination was best. Table 9 also lists the friction and wear for the same material combinations in the presence of SDL-1, a formulated SAE 15W-30 commercial lubricant. The steel/nickel aluminide combination was benefited most by the presence of the lubricant. The alumina pins wore the least under the lubricated conditions, and they produced the highest wear of the nickel aluminide. Therefore, of the two ceramics (silicon nitride and alumina), the silicon nitride/nickel aluminide combination produced the lowest system (total) wear, especially in the case of IC-396M.

Table 9 Reciprocating ball-on-flat friction and wear data for two nickel aluminide alloys at room temperature in air

Test parameters: load, 25.0 N (2.55 kgf); oscillation frequency, 10.0 Hz; stroke length, 10.0 mm (0.394 in.); slider bar diameter, 9.53 mm (0.375 in.)

Parameter	Slider ball material

Unlubricated						
Friction coefficient[(a)]	0.80	0.80	0.72	0.80	1.13	1.08

Wear factor [(mm³/N · m) × 10⁻⁷][(b)]:						
Ball	560	590	140	140	660	1000
Flat	78	250	75	80	290	380
Lubricated (SDL-1 commercial lubricant 15W-30)						
Friction coefficient	0.07	0.13	0.06	0.10	0.06	0.09
Wear factor[(b)], (mm³/N · m) × 10⁻⁷						
Ball	NM[(c)(d)]	NM[(c)]	0.56	0.26	0.18	0.11
Flat	4.7	3.3	4.5	1.9	0.6	0.39

(a) Root-mean-square at steady state averaged for at least two tests. Actual value may vary by as much as 25%.

(b) Average value for at least two tests. Test-to-test values may vary by as much as 50%.

(c) NM, not measurable.

(d) Not measurable due to the absence of a discernible flat spot on the pin tip

Cylindrical rods, 6.0 mm (0.24 in.) in diameter, of IC-50 and IC-396M alloys were used for reciprocating tests with the cylinder-on-flat geometry. In each case, the long axis of the 10 mm (0.39 in.) long cylinders was fixed perpendicular to the sliding direction, and a rectangular scar was produced along the length of the cylinder. These rod materials were run against flats of the same materials. The hardness of the cylinders tended to be higher than that of the flats (see Table 4). As Table 10 data show, the flat specimens of IC-396M wore less than those of IC-50 at both test temperatures. Because the wear of the cylindrical specimens was similar in all tests, the total system wear, coupled with the slightly lower friction, makes IC-396M the best performer in these tests.

Table 10 Unlubricated reciprocating cylinder-on-flat friction and wear data for two self-mated nickel aluminide alloys

Parameters[(a)]	Test temperature			
	25 °C (75 °F)		**200 °C (390 °F)**

(b) Root mean square at steady state averaged for at least two tests. Actual value may vary by as much as 25%.

(c) Average value for at least two tests. Test-to-test values may vary by as much as 50%.

(d) NM, not measured

Sliding Wear Properties of Nickel Aluminide Alloys. Based on limited test data for nickel aluminide alloys in laboratory conditions, there appears to be a potential for these alloys in high-temperature friction and wear applications. However, a great deal more development work and field trials, aimed at specific wear applications, must be conducted before specific recommendations can be made.

Future Outlook

Nickel aluminide alloys are strong, tough, high-temperature-resistant materials that may find selected applications in wear-critical applications, especially where their corrosion resistance and high-temperature properties may also be a factor. Only very limited friction and wear data exist for these alloys, and more work is needed, including field trials and cost analyses, before widespread commercial tribological applications are likely to appear.

Friction and Wear of Titanium Alloys

F.M. Kustas and M.S. Misra, Martin Marietta Astronautics Group

Introduction

TITANIUM ALLOYS offer an attractive combination of high specific mechanical properties, such as modulus/density and strength/density, because of their relatively low density. Titanium alloys also have high toughness and corrosion resistance, making them useful materials for precision mechanism gears, turbine engine components, and biomedical prosthesis devices. However, these alloys have poor fretting fatigue resistance and poor tribological properties. From theoretical calculations, metals with low theoretical tensile and shear strengths exhibit higher coefficients of friction (μ) than higher-strength materials (Ref 1). Within the class of hexagonal close-packed (hcp) structures, titanium has relatively low values for these properties. Consequently, it is expected that titanium would exhibit high frictional values, which has been demonstrated for titanium sliding against itself in air (μ = 60, Ref 1) and vacuum (Fig. 1) (Ref 2).

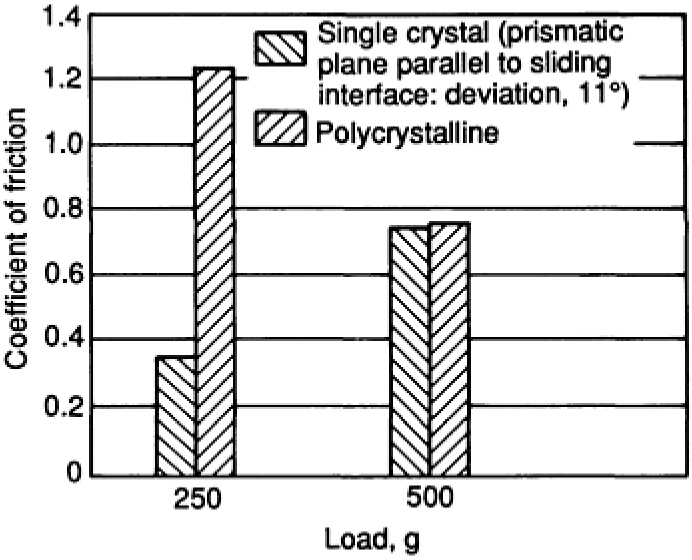

Fig. 1 Coefficient of friction for single-crystal and polycrystalline titanium sliding on polycrystalline titanium in vacuum. Pressure, 1.33 × 10^{-7} Pa (10^{-9} torr); sliding speed, 2.28 cm/s (0.90 in./s). Source: Ref 2

Lower-tensile-strength materials, including titanium, also exhibit greater material transfer to nonmetallic counterfaces than higher-strength metals (Ref 1). The great affinity of titanium for oxygen results in the formation of an oxide surface layer, which is transferred to and adheres to nonmetallic materials, such as polymers, resulting in severe adhesive wear (Ref 2). Addition of a lubricant, such as polyperfluoroalkylether (PFPE) (Ref 3) or kerosene oil (Ref 4), reduces the coefficient of friction and wear damage somewhat, compared with unlubricated conditions Fig. 2) (Ref 3, 4, 5), although reaction of titanium surfaces with these lubricants (generally under high-temperature conditions) can reduce lubricant performance (Ref 6).

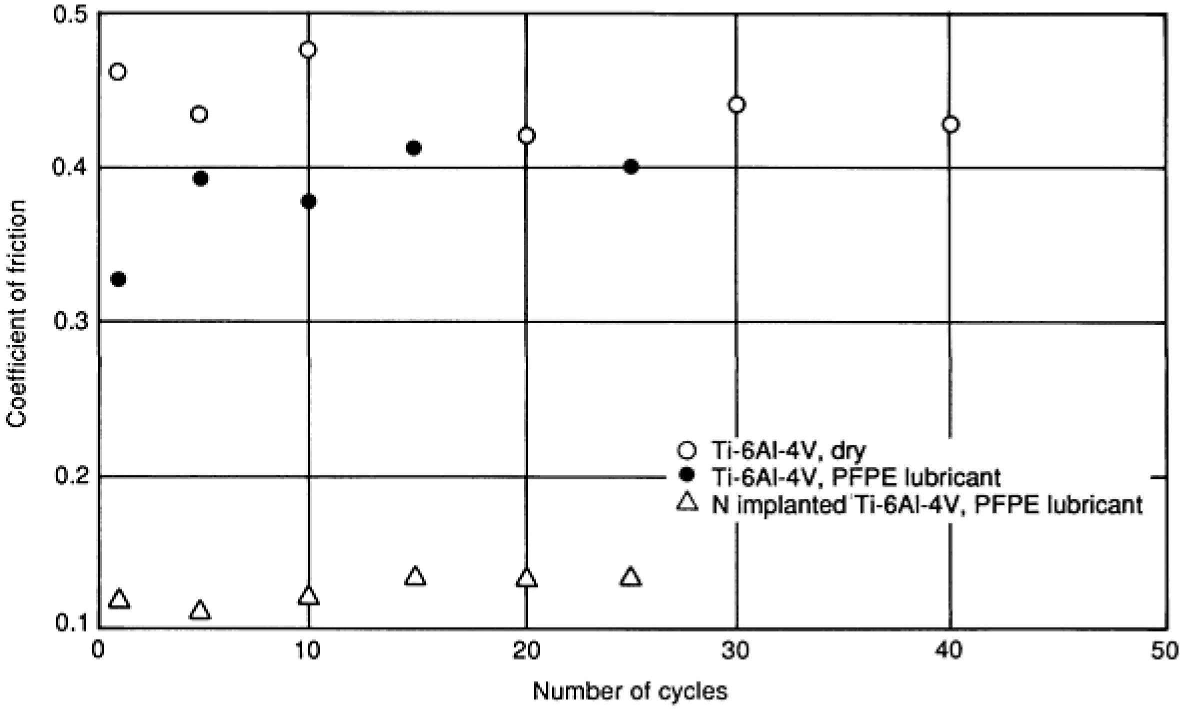

Fig. 2 Reduced coefficients of friction for PFPE-lubricated Ti-6Al-4V compared with unlubricated Ti-6Al-4V in air

environment. Sliding material, WC-Co; sliding speed, 1 mm/s (0.04 in./s); load, 0.5 kgf. Source: Ref 3, 5

Although titanium alloys offer attractive mechanical and physical properties, their surface properties are deficient, thus restricting the use of uncoated titanium alloys to nontribological applications. To realize the full benefit of titanium alloys in friction and wear applications, surface modification treatments are required to effectively increase near-surface strength, thereby reducing the coefficient of friction and lowering the tendency for material transfer and adhesive wear.

Surface Modification Treatments

Many surface treatments have been used to modify the tribological properties of titanium alloys. These treatments can be classified as physical vapor deposition (PVD), including ion implantation (Ref 5, 6, 7, 8, 9, 10, 11, 12, 13), plasma spray (Ref 15, 16), and evaporation (Ref 4); thermochemical conversion treatments, including plasma nitriding (Ref 17, 18), gaseous nitriding (Ref 19), liquid nitriding (Ref 20), ionic nitriding (Ref 21), laser nitriding (Ref 22), ionic carburizing (Ref 21), and laser boriding (Ref 22); plating (Ref 17, 20, 23); and application of solid lubricants by resin bonding/burnishing (Ref 20, 23), direct ion beam deposition to produce diamond-like carbon (DLC) (Ref 24), and sputtering (of molybdenum disulfide and titanium nitride, for example) (Ref 18, 25, 26). These treatments differ dramatically with respect to induced surface temperatures, with nearly ambient conditions for low-dose-rate ion implantation and ion-beam deposition, while temperatures up to 900 °C (1650 °F) are common for plasma nitriding and carburizing treatments. Table 1 summarizes the major advantages and limitations of the various surface modification treatments for titanium alloys.

Table 1 Advantages and limitations of surface modification treatments for titanium alloys

Surface modification technique	Advantages	Limitations
Physical vapor deposition		
Ion implantation	Low-temperature process; effectively net shape; creation of unique near-surface alloys; gradual interface	Line of sight; shallow surface modification zone; high cost
Plasma spray	Rapid deposition rates; thick coatings; inherent porosity can trap lubricant; low cost	Coarse surface finish; need for bond layer, abrupt interfaces; hard-to-control coating composition; line of sight
Evaporation	Large range of available materials; tailorable compositions; high-purity coatings; low cost	Thin coatings; line of sight; abrupt interface (unless ion-beam assisted)
Sputtering	Low-temperature process; potential for layered coatings; tailored coating composition	Thin coatings; line of sight; abrupt interface (unless ion-beam assisted)
Thermochemical conversion		
Nitriding, carburizing, boriding	Gradual interface, conversion of substrate; thick surface modification zones	Potential for hydrogen embrittlement restricts selection of titanium alloys; high process temperatures can distort components and reduced properties; coarse surface finish
Plating	Not line of sight; low cost	Potential for hydrogen embrittlement restricts selection of titanium alloys; abrupt interface

Physical Vapor Deposition

Physical vapor deposition includes ion implantation, sputtering, evaporation, and ion plating surface modification treatments.

Ion implantation is a low-temperature technique for modifying the near-surface region of a material. The modified zone is incorporated within the substrate, leaving no defined interface. The process is a line-of-sight technique and generally offers only shallow penetration depths.

Studies of ion-implanted titanium alloys have concentrated on carbon, nitrogen, and nitrogen-oxygen implantations to produce surfaces enriched in TiC, TiN and Ti_2N, and Ti-O-N, respectively. From pin-on-disk friction wear tests, much greater (that is, two orders of magnitude) wear resistance has been shown (Fig. 3) for nitrogen-implanted Ti-6Al-4V compared with untreated material (Ref 7). Nitrogen or carbon implanted into pure titanium produces nearly equivalent results for breakthrough load to failure of the ion-implanted zoned (defined as applied load for failure of the surface after

fewer than 50 revolutions of the implanted disk) (Fig. 4) (Ref 7). In contrast, nitrogen implantation of higher hardness and higher-strength Ti-6Al-4V is more effective than carbon implantation in increasing breakthrough load (Fig. 4).

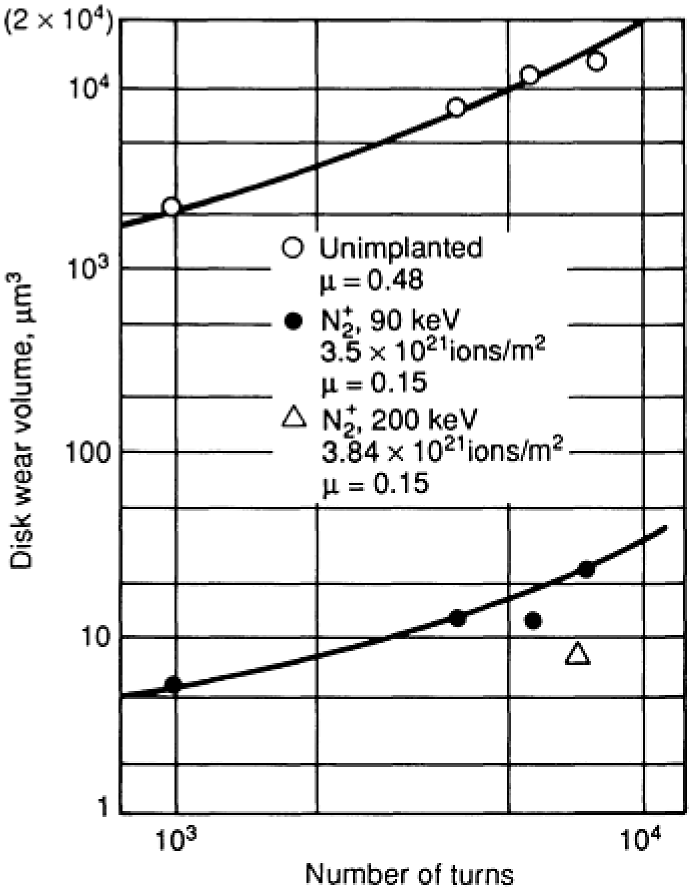

Fig. 3 Wear volume loss as a function of cycles for untreated and nitrogen-implanted Ti-6Al-4V, showing greater than two orders of magnitude reduction in volume loss for nitrogen-implanted material. Pin, 5 mm (0.2 in.) ruby ball; load, 2.61 N (0.266 kgf); velocity, 5.65 mm/s (2.2 in./s). Source: Ref 7

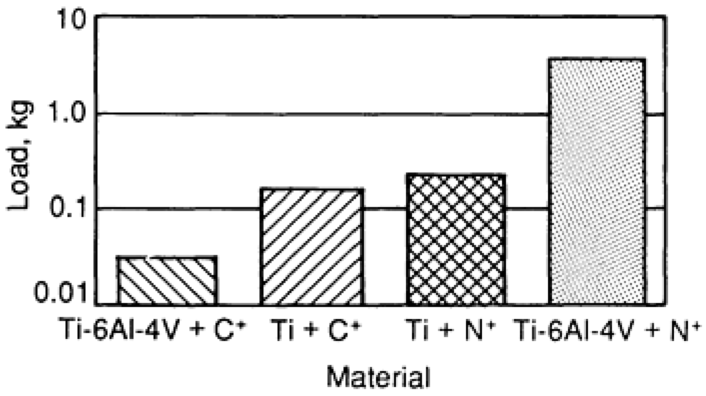

Fig. 4 Breakthrough load for four titaniuim substrate-ion combinations. Pin, 5 mm (0.2 in.) ruby ball; velocity, 56.6 mm/s (2.23 in./s). Source: Ref 7

Additional studies (Ref 8, 9) have shown that (I) an optimum heat treatment of about 400 to 470 °C (750 to 880 °F) after carbon implantation results in greater cycles to breakthrough (an increase by a factor of 30 compared with room-temperature implantation) because of formation of 60 nm diameter TiC particles and (2) a dual-energy implant (to

produce deeper nitrogen penetration) will significantly increase the wear life (by at least one order of magnitude) (Ref 8) of the implanted zone. Carbon implantation increases fretting fatigue life (Fig. 5) by slowing the formation of debris that causes surface damage and subsequent crack initiation (Ref 10).

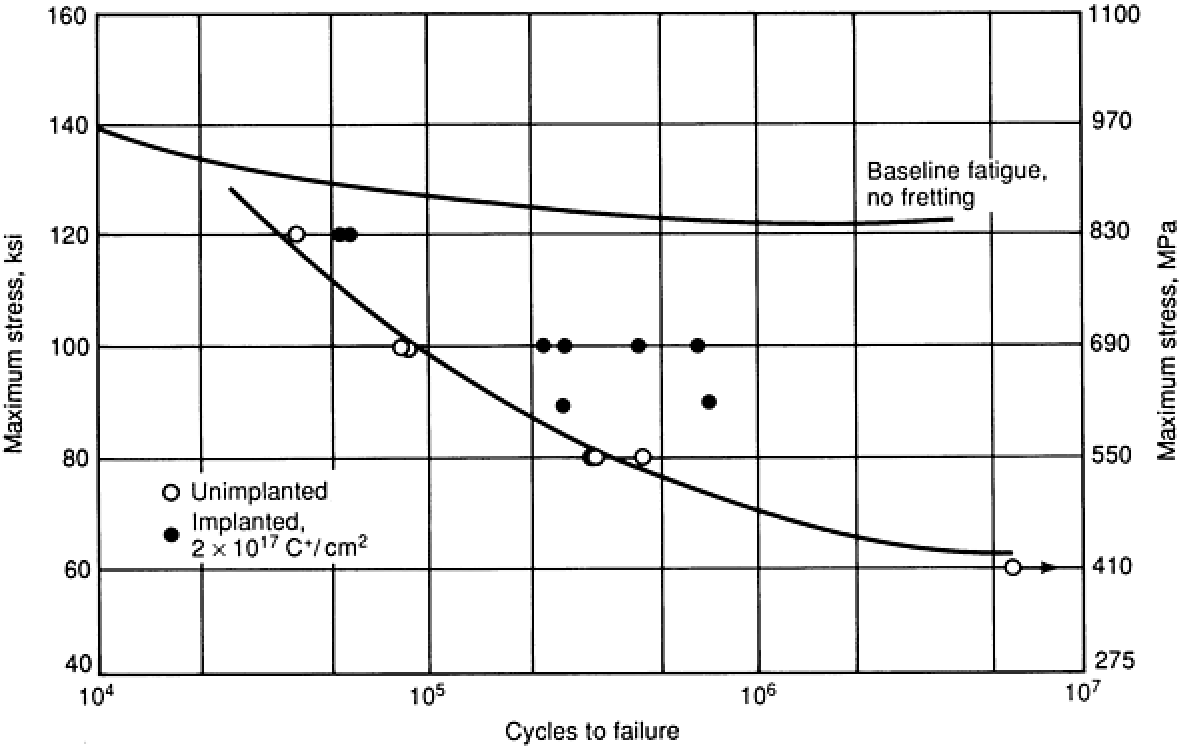

Fig. 5 Cycles to failure versus maximum fatigue stress for carbon-implanted and unimplanted Ti-6Al-4V. Normal stress, 690 MPa (100 ksi); baseline fatigue (no fretting) data, 20.7 MPa (3 ksi). Source: Ref 10, 27

Modification of surface composition enhances the tribological properties of deficient materials. Quantitative analyses of worn surfaces on nitrogen-implanted Ti-6Al-4V have shown that oxygen and carbon are incorporated into the surface layer during either implantation or the wear event. These complex-composition surface layers help produce lower coefficients of friction (Ref 11, 12).

Implantation of Ti-6Al-4V has been performed to improve its corrosive wear resistance when in contact with ultrahigh-molecular-weight polyethylene (UHMWPE) (Ref 13). This combination of materials is used for biomedical prostheses, such as artificial hips (Ref 28), where an integral stem and ball of Ti-6Al-4V is in contact with a UHMWPE acetabular cup. Flakes of TiO_2 formed during wear of titanium in contact with UHMWPE may result in adverse tissue response, including inflammation, infection, loosening of the prosthetic component, and possible carcinogenic reaction. Implantation of Ti-6Al-4V with nitrogen to produce a 20% surface concentration reduced corrosion current in an oxygen-saturated sodium chloride isotonic salt solution by 100 times compared with unimplanted Ti-6Al-4V. The wear surface of the nitrogen-implanted Ti-6Al-4V, in contact with UHMWPE pads, exhibited only a few black stripes after the test--in contrast to the wear surface of unimplanted Ti-6Al-4V, which was completely blackened early in the testing. The authors concluded that the black debris was TiO_2 embedded in the UHMWPE that was transferred to the Ti-6Al-4V surface (Ref 13). In a related study, nitrogen or carbon implantation of Ti-6Al-4V significantly reduced the wear volumes (by five times) of both the pin (Ti-6Al-4V) and the rotating disk (UHMWPE) under a screening environment of Ringer's solution (a lactated 0.9% NaCl solution with the same concentration of Cl^- ions as in body fluids) (Ref 14).

Recently, high-temperature nitrogen implantation of Ti-6Al-4V has been evaluated as a means of increasing the penetration depth of nitrogen into a titanium alloy substrate. It has been demonstrated that the most beneficial tribological properties occur for a 1000 °C (1830 °F) implantation of 10^{18} N_2^+-N^+/cm^2 at 60 keV. This treatment produced the deepest penetration of nitrogen (>750 nm) along with the formation of TiN and Ti_2N (Ref 29). Lowest unlubricated coefficient of friction values (down to about 0.12) were observed for this specimen, with μ decreasing with increasing

applied load until a critical load of 98 N (22 lbf), at which implanted layer failure occurred (Ref 5). Under PFPE lubricated conditions, a threefold reduction in coefficient of friction was observed compared with nonimplanted Ti-6Al-4V for a 600 °C (1110 °F) nitrogen implantation treatment of 10^{17} N_2^+ -N^+/cm^2 at 75 keV (Fig. 2) (Ref 5). The high ion-beam current densities employed during the processing (up to 500 μA/cm^2 versus <50 μA/cm^2 for conventional ion implantation) results in short-time beam exposures of only a few minutes at the elevated temperatures (Ref 29), which would not degrade bulk material properties.

Plasma Spray Coatings. Evaluation of the wear and fatigue performance of spherical bearing components with candidate coatings on Ti-10V-2Fe-3Al showed that plasma spray coatings of Cr_2O_3, Al_2O_3, and WC were the most wear resistant and exhibited the lowest torques (Table 2) (Ref 16). Test results using lubricants contaminated with road dust illustrated the superiority of plasma spray Cr_2O_3 on Ti-10V-2Fe-3Al compared to chromium-plated was 15-5 PH steel where the chromium plating was completely removed during testing. Finally, grease-starved (after initial lubrication) tests showed superior performance for plasma-sprayed Al_2O_3 and WC coatings, which remained intact after 100,000 cycles without addition of grease. The porosity of these coatings served as lubricant reservoirs, providing grease replenishment during the test. As a result, Cr_2O_3-coated titanium components have been incorporated into forward trunnion spherical bearings for aircraft landing gear.

Table 2 Normal lubrication bearing test results for plasma-spray-coated Ti-10V-2Fe-3Al

Bearings were lubricated every 900 cycles with clean grease per MIL-G-23827.

Bearing substrate/coating	Bearing stress		Torque				Cycles	Comments
			At 100 cycles		At end of test			
	MPa	ksi	N · m	lbf · in.	N · m	lbf · in.

Evaporation. Hard coatings such as TiC, TiN, and Ti_2N deposited on titanium disks by activated reactive evaporation (ARE) have been evaluated against different mating rider materials such as 440C steel, TiC/440C steel, and TiN/440C steel under dry and lubricated (for example, kerosene oil) conditions (Ref 4). In general, the following conclusions can be drawn from the tribological data (Table 3):

- Coefficients of friction and wear volumes (for both rider and disk) are high for both bare and coated 440C steel versus bare titanium
- Coefficients of friction and titanium disk wear volumes are much lower for bare 440C steel versus coated titanium
- Coefficients of friction and wear volumes are lowest for hard coatings on both 440C steel riders and titanium disks

A material combination of TiN/440C rider versus TiC/Ti disk gave the best performance, although the reverse coating combination was not as effective (Table 3).

Table 3 Coefficients of friction and rider and disk wear for various wear couple combinations for uncoated and hard-ceramic-coated titanium

All tests run for 500 m (1640 ft) under a load of 0.4 kg (0.9 lb), unless otherwise noted

Rider	Disk	Coefficients of friction[a]			Rider wear[b]		Disk wear[c]	
		μ_S	μ_D	μ_L	**Dry**	**Lubricated[d]**	**Dry**	**Lubricated[d]**
440C steel, uncoated	Ti, uncoated	0.765	0.45	0.425	High	High	High	High
	TiC/Ti	0.175	0.275	0.275	Medium	High	Low	Low
	TiN + Ti_2N/Ti	0.2	0.35	0.275	High	High	Low	Low
TiC/440C steel	Ti, uncoated	0.65	0.8	0.5	High	. . .	High	. . .
	TiC/Ti	0.275	0.175	0.175	Low	Low	Low	Low
	TiN + Ti_2N/Ti	0.275	0.2	0.1	Low	Low	Low	Low
TiN/440C steel	Ti, uncoated	0.5	0.765	0.4	High	Medium	High	High
	TiC/TiN	0.05	0.025	0.15	Low[e]	Very low	Low	Low

(a) μ_S, static coefficient of friction measured when disk began to slide (velocity: 1.2-1.5 cm/s, or 0.5-0.6 in./s); μ_D, dynamic coefficient of friction measured after about 10 disk revolutions (velocity: 10-15 cm/s, or 4-6 in./s); μ_L, lubricated coefficient of friction measured after about 10 disk revolutions (velocity: 10-15 cm/s, or 4-6 in./s).

(b) Wear test speed was 22-25 cm/s (8.5-10 in./s). Wear volumes are defined as: high, >5 × 10^{-3} mm^3 (3 × 10^{-3} $in.^3$); medium, 10^{-4} to 5 ×10^{-3} mm^3 (0.6 × 10^{-4} to 3 × 10^{-3} $in.^3$); low, 10^{-5} to 10^{-4} mm^3 (0.6 × 10^{-5} to 0.6 × 10^{-4} $in.^3$); very low, <10^{-5} mm^3 (0.6 × 10^{-5} $in.^3$).

(c) Wear test speed was 22-25 cm/s (8.5-10 in./s). Wear volumes are defined as: high, >2.54 × 10^{-3} mm^3 (1.55 × 10^{-3} $in.^3$); medium 2.54 × 10^{-4} to 2.54 × 10^{-3} mm^3 (1.55 × 10^{-4} to 1.55 × 10^{-3} $in.^3$); low, <2.54 × 10^{-4} mm^3 (1.55 × 10^{-4} $in.^3$).

Thermochemical Conversion Surface Treatments

Nitriding, Carburizing, and Boriding. Ionic nitriding and carburizing offer the advantage of producing deeper nitride case depths (up to about 6 μm thick) due to thermal diffusion at elevated temperatures (750 to 900 °C, or 1380 to 1650 °F) (Ref 21). These treatments generally are applied to annealed Ti-6Al-4V and pure titanium. An adverse effect of irreversible grain growth was observed to be most prevalent for a 900 °C (1650 °F) treatment (Ref 21). Large-grain microstructures generally have lower mechanical properties than fine-grain material.

Hydrogen-containing compounds, often used in the nitriding process, provide a source of hydrogen that can diffuse into the titanium alloy substrate during the high-temperature nitriding operation. For titanium alloys, the effects of hydrogen contamination on mechanical properties are highly dependent on the specific phase of the titanium alloy microstructure. For example, α-phase titanium alloys are prone to titanium hydride formation (Ref 21), which can embrittle the matrix and thereby reduce mechanical properties. In contrast, titanium alloys with a β-phase microstructure maintain hydrogen in solid solution, which minimizes embrittlement but results in a lower hardening tendency (Ref 21).

Tribological properties of plasma-nitrided titanium alloys are very impressive. Low coefficients of friction (0.05 to 0.08) and low wear rates have been demonstrated for plasma-nitrided Ti-6Al-4V compared with untreated material (Fig. 6) (Ref 18). Fatigue performance of the nitrided material is highly dependent on prior substrate condition. Annealed Ti-6Al-V that was subsequently nitrided showed a marked reduction (up to 21%) in endurance life compared with untreated Ti-6A1-4V; this can be attributed to coarsening of the αgrains and production of a continuous αmatrix (Ref 18). Use of a solution-treated and aged material, however, reduced the fatigue degradation to only 4% for the nitrided material (Ref 18).

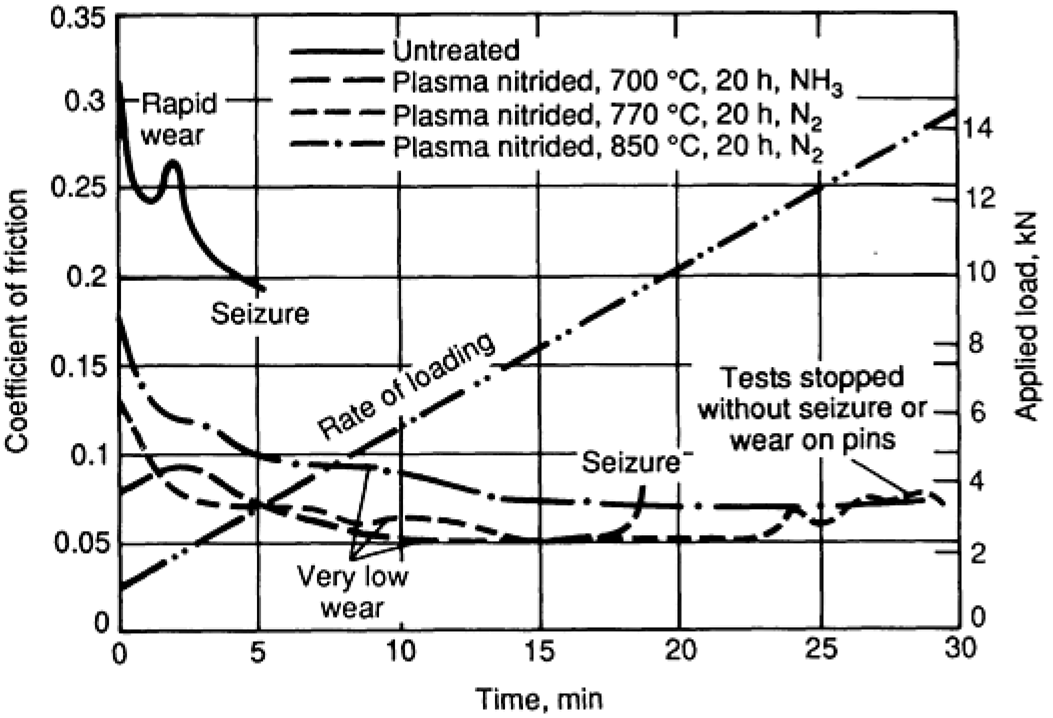

Fig. 6 Wear test results for untreated and plasma-nitrided Ti-6Al-4V. Source: Ref 18

Laser Surface Treatments. Laser surface heating and introduction of hard particles into the surface via reaction with gas (such as nitrogen or methane) or heating of surface deposit (graphite or boron nitride) have been used to produce thick nitride and boride surfaces (Ref 22). Erosion resistance (based on mass loss) of a laser-nitrided Ti-6Al-4V specimen against SiC particles was greater compared with untreated Ti-6Al-4V (Fig. 7). The laser-nitrided layer delays the onset of steady-state erosion that is characteristic for an uncoated Ti-6Al-4V surface. As shown in Fig. 7, the laser-nitrided layer is intact for a lower number of impacts, then suffers fracture and becomes embedded in the substrate as the number of impacts increases. Eventually, a sufficient number of impacts removes the laser-nitrided layer, exposing the uncoated Ti-6Al-4V substrate and resulting in steady-state erosion. In comparison, a TiN layer on a PVD-coated Ti-6Al-4V specimen was removed after only a few impacts.

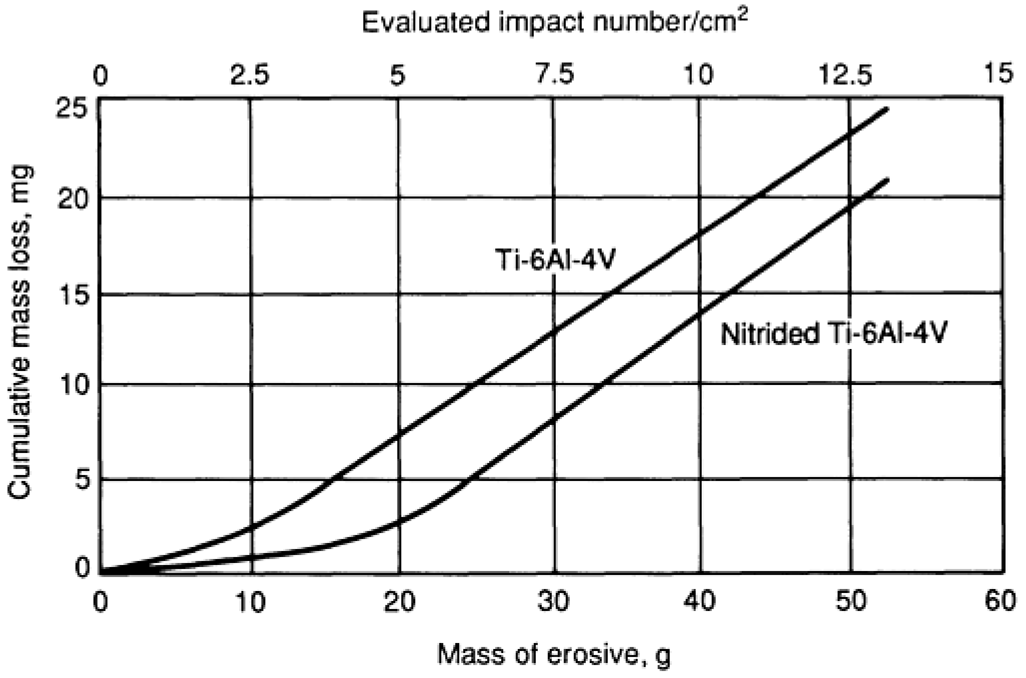

Fig. 7 Cumulative mass loss curves for Ti-6Al-4V and laser-nitrided Ti-6Al-4V. Source: Ref 22

Boride coatings on titanium alloys have shown good resistance to high-velocity particle impacts (Ref 22). Very thick (up to 80 μm), dense coatings have been produced on Ti-6Al-4V by laser boriding. Erosion rates of these thick coatings are reduced, because the material removal mechanism is modified to one of coating cracking rather than erosion of surface material.

Solid Lubrication

Solid lubricants are solid-state materials (generally layered lattice compounds) that are applied to a surface by a burnishing operation (with an organic bonding agent) or deposited by plating or sputtering. Applications for solid-lubricant-coated titanium tribomaterials include components such as compressor blades, uniball bearings, and bearing seal rings for gas turbine engines (Ref 23) and gears for spacecraft mechanism actuators (Ref 17). For the former application, pulse plating deposition of Cr-Mo on Ti-6Al-4V and Ti-8Al-1Mo-1V was performed to produce a solid solution surface layer of Cr-Mo-Ti, which exhibited no degradation of substrate properties, increased creep life by up to 50%, and oxidation protection to 760 °C (1400 °F) (Ref 23). Commercial solid lubricant coatings were subsequently applied to the Cr-Mo-coated/Ti-6Al-4V specimens. Unlubricated wear tests on the solid-lubricant-coated Cr-Mo/Ti-6Al-4V specimens were performed by running them against AISI 1137 steel V-blocks. Test results showed excellent wear resistance for several of the solid lubricant surface treatments (Table 4) (Ref 23). The best performer was PWA 36035 (Fel-Pro C-300: 50% solvent, 47% MoS_2, 3% graphite and other solids). Solvent compatibility tests, however, showed this coating to have poor resistance to jet fuel and oil. Cr-Mo-coated titanium alloy uniballs tested for 520 h in an engine simulator demonstrated no failures, in contrast to a 30% failure rate for standard steel uniballs.

Table 4 Wear tests using Cr-Mo-coated Ti-6Al-4V pins and uncoated steel V-blocks

Solid lubricant	Average time to failure at specified load, min				
	1330 N (300 lbf)	**2220 N (500 lbf)**	**3330 N (750 lbf)**	**4450 N (1000 lbf)**	**Standard deviation**

Source: Ref 23

(a) Standard deviations for these tests are misleading, because each set included at least one pin that failed to reach 4450 N (1000 lbf).

Other potential aerospace applications of titanium alloys include drive mechanism components and launch locks (mechanisms used to distribute the load induced by an aerospace vehicle launch through an alternate load path). Replacement of steel gears with titanium alloy gears would reduce subsystem weight and result in reduced launch costs. The effects of various surface treatments on the wear life and efficiency of annealed Ti-6Al-4V gears have been studied by vacuum testing (Ref 17). As shown in Fig. 8, boronized (5 μm layer of metallic borides), Tifran (5 μm layer of complex oxides), and ion-plated aluminum coatings exhibited the best wear resistance and the lowest power losses.

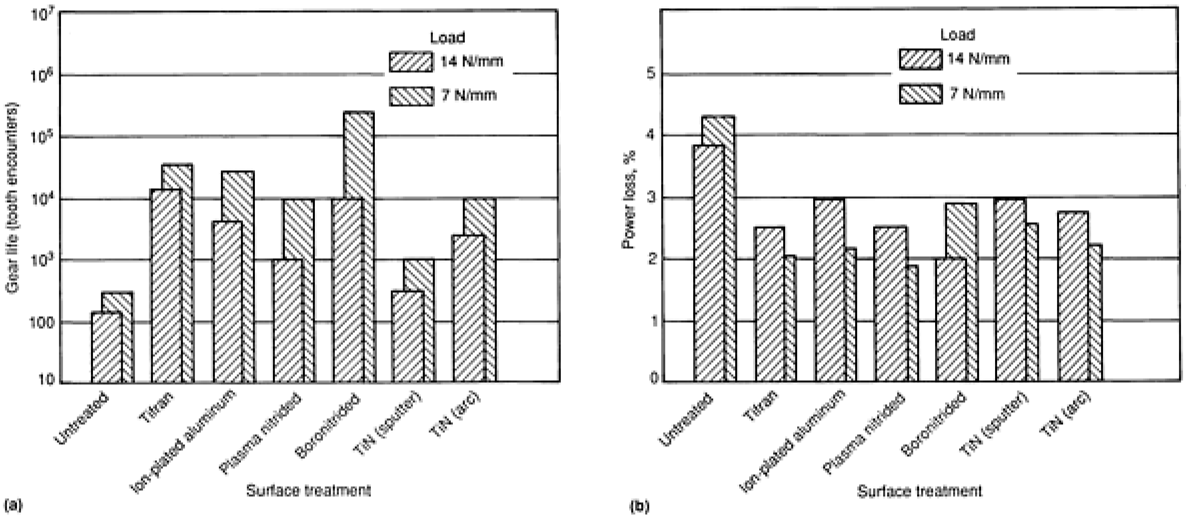

Fig. 8 Performance of surface-treated Ti-6Al-4V gears. (a) Effective life. (b) Effective gear efficiency. Source: Ref 17

The fabrication of solid lubricants such as diamondlike carbon (Ref 24) and molybdenum disulfide (Ref 25, 26) has also been studied. Diamondlike carbon coating exhibits very high hardness and solid lubricant behavior because of its graphite and amorphous carbon contents. To facilitate good DLC adhesion on Ti-6Al-4V, an intermediate bond layer of SiC is required (Ref 24). Unlubricated sliding wear tests in air of DLC/SiC/Ti-6Al-4V against a WC-CO pin showed a gradual reduction in coefficient of friction (down to 0.15) with increased load (Fig. 9) (Ref 24). Diamondlike carbon coating performed very well up to an initial stress level of 1.7 GPa (245 ksi) (52% above the yield strength of the Ti-6Al-4V substrate), at which DLC delamination was observed (Fig. 9).

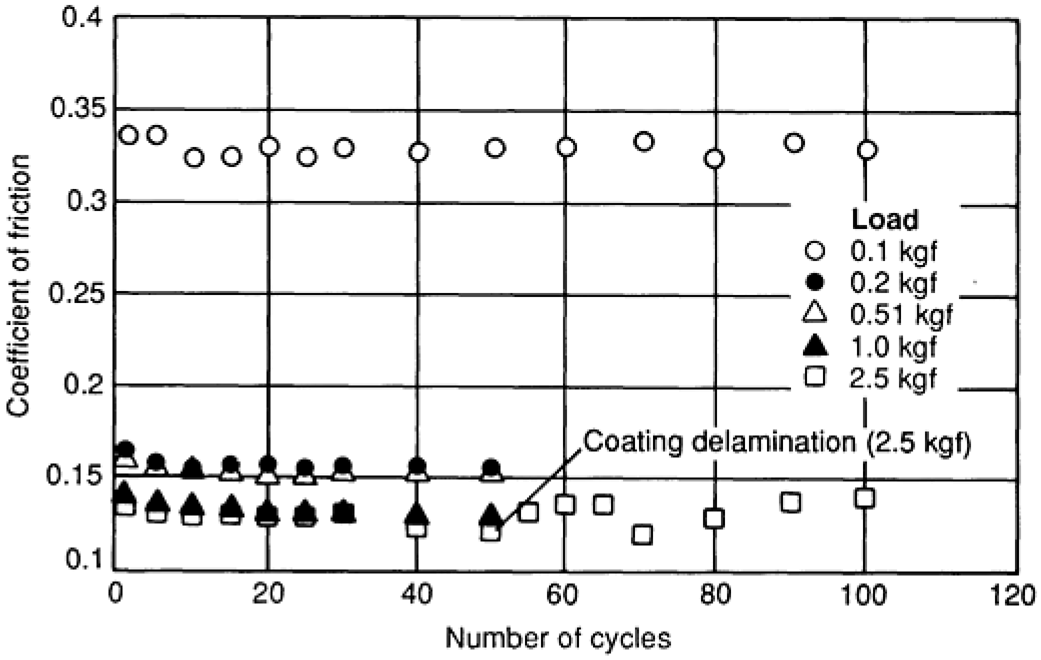

Fig. 9 Coefficient of friction versus wear cycles for 2.5 μm DLC/0.02 μm SiC interlayer coating on Ti-6Al-4V, showing reduction in μ with increased load. Sliding materials, WC-CO; sliding speed, 2 mm/s (0.08 in./s). Source: Ref 24

Coating of titanium alloys with sputtered layered lattice solid lubricants, such as MoS_2, reduces their tendency to gall. Initial studies showed that MoS_2 adhesion to Ti-6Al-4V is very poor, as evidenced by the relatively low vacuum endurance life for MoS_2-coated Ti-6Al-4V loaded against itself (1.7 kgf load, 1.2 m/s sliding speed) of only about 600 revolutions (about 113 m sliding distance) (Ref 25). This is several orders of magnitude lower than for MoS_2-coated steel or ceramic (Si_3N_4) substrates (Fig. 10) (Ref 25).

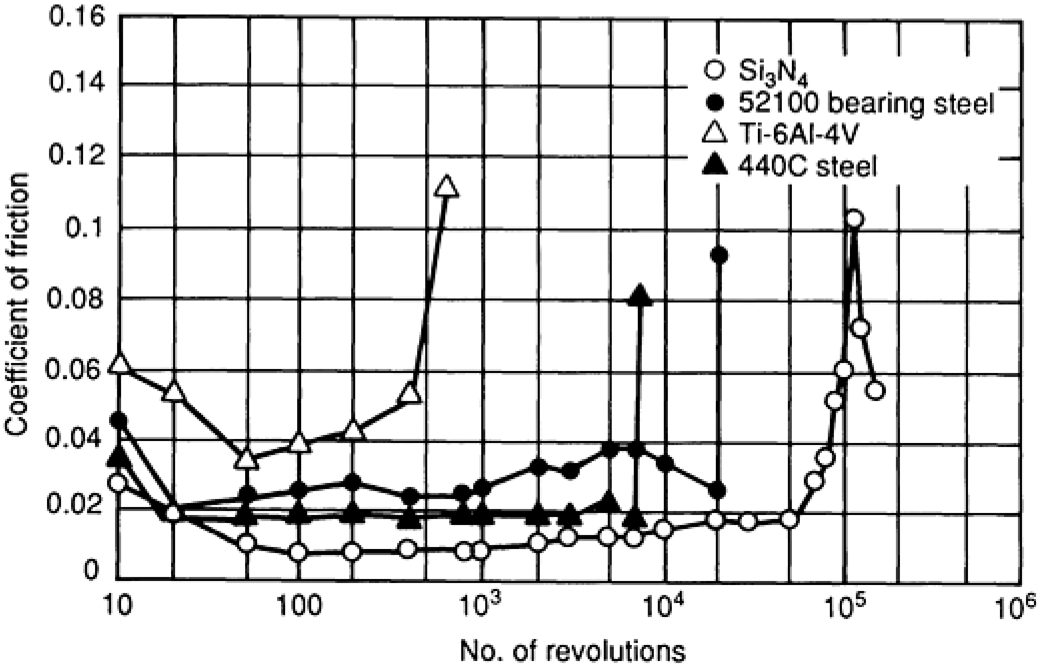

Fig. 10 Endurance lifetimes of MoS_2 on various substrates, showing longest lifetimes for Si_3N_4 and 52100

bearing steel. Sliding material, Ti-6Al-4V; sliding speed, 1.2 m/s (3.9 ft/s); applied load, 17 N/ball (1.7 kgf/ball). Source: Ref 25

Additional research has shown that pretreating the Ti-6Al-4V surface using a nitrogen implantation process produces a ceramic TiN/Ti_2N surface, which significantly increases the load-carrying capacity and high-load endurance lifetime of the sputtered MoS_2 coating on Ti-6Al-4V loaded against steel in an air environment (2 mm/s sliding speed) (Ref 26). Figure 11 shows the relative endurance lifetimes, as a function of applied load, for MoS_2-coated Ti-6Al-4V and MoS_2-coated nitrogen-implanted Ti-6Al-4V specimens. For MoS_2-coated Ti-6Al-4V, a gradual reduction in endurance life from more than 300 reciprocating cycles (5 and 6 kgf loads) to 33 cycles (6.5 kgf load) to 15 cycles (7 kgf load) to nearly instantaneous failure (7.5 kgf load) was observed. In contrast, for the best nitrogen implantation pretreatment of 2×10^{17} $N_2^+ - N^+/cm^2$ at 75 keV (400 °C, or 750 °F, surface temperature), no MoS_2 coating failures were observed for test loads up to the 122.5 N (27.5 lbf) load limit of the test machine. This significant improvement in load-carrying capacity and high-load endurance life has been attributed to improved MoS_2 adhesion to the TiN/Ti_2N-rich Ti-6Al-4V surface through an irradiation-disrupted titanium oxide (Ref 26).

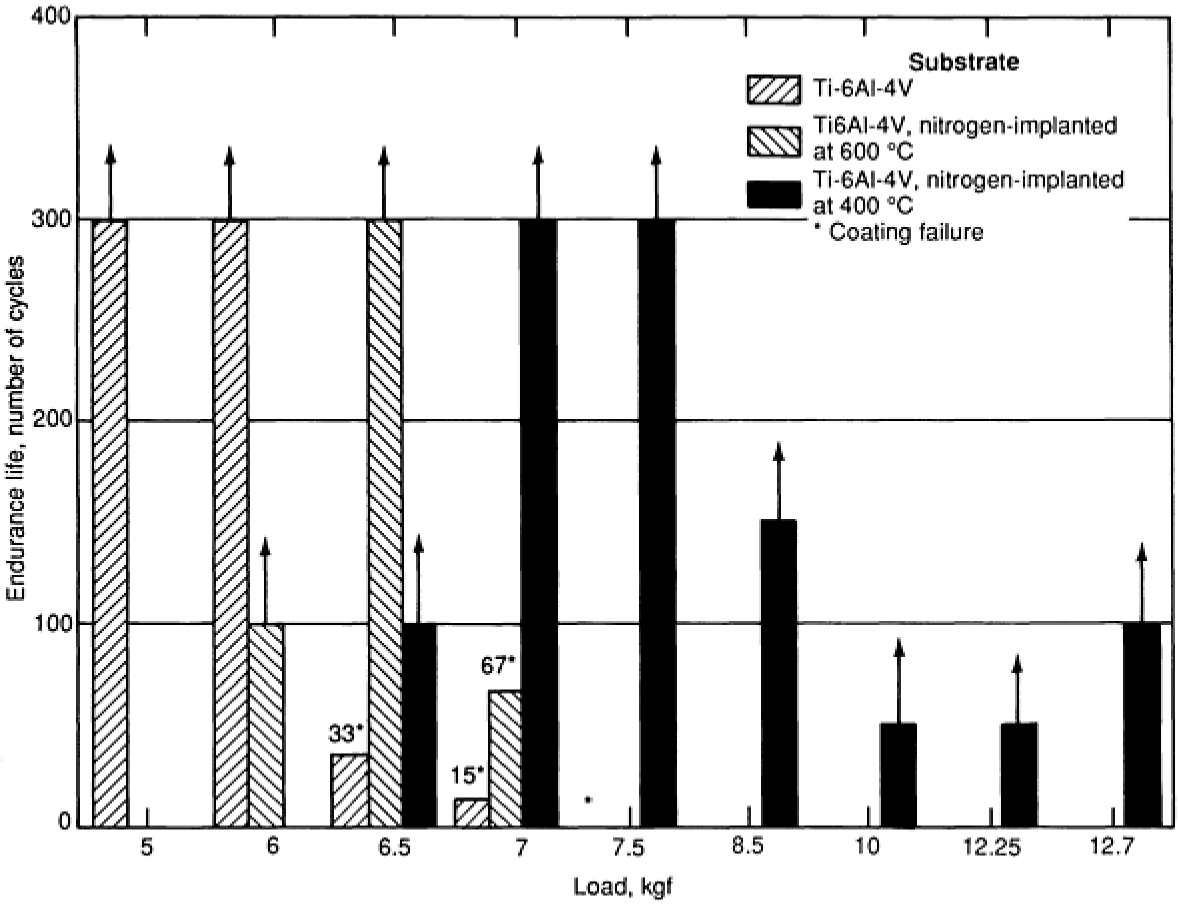

Fig. 11 Endurance lifetimes of MoS_2-coated Ti-6Al-4V specimens, showing significantly increased lifetimes (at high loads) for MoS_2 coating on nitrogen-implanted (processed at 400 °C, or 750 °F) Ti-6Al-4V substrate. Friction and Wear of Aluminum-Silicon Alloys

Barrie S. Shabel, Douglas A. Granger, and William G. Truckner, Alcoa Technical Center

Introduction

ALUMINUM-SILICON ALLOYS are noted for their unique combination of desirable characteristics, including excellent castability and low density combined with good mechanical properties. Interestingly, there is no mention of wear resistance in the many published tabulations of the attributes of this class of alloys (see, for example, Ref 1 and 2). In a comprehensive review of the wear characteristics of aluminum alloys, Eyre (Ref 3) remarks on the dearth of published information about the wear resistance of aluminum-silicon alloys, while acknowledging their increased application in environments demanding this physical characteristics.

In the late 1950s, die cast aluminum-silicon alloy cylinder blocks were manufactured for the automotive industry to take advantage of the light weight and good thermal conductivity offered by hypoeutectic alloys such as A356 and A380 (Ref 4). However, because these alloys exhibited only modest wear resistance, the early engine blocks (for example, those produced for the American Motors Corporation Rambler) had a cast-in steel cylinder liner. In Europe, automotive engine blocks were also being die cast in aluminum-silicon alloys (such as LM24 and LM26), but these blocks had liners that were shrink-fitted in place. A major boost was given to the use of lightweight aluminum alloys in automobiles when the energy crisis in the early 1970s resulted in the government mandating improved fuel consumption in automobiles. Because fuel consumption can be directly related to vehicle weight (Ref 5), the use of aluminum in place of cast iron in engine components became highly desirable. However, the use of die cast aluminum engine blocks with a cast iron cylinder liner proved to be too costly in production, paving the way for the development of hypereutectic aluminum-silicon alloys with greater wear resistance that could be used without liners.

One such alloy that has been developed specifically for its high wear resistance is the hypereutectic aluminum-silicon alloy A390 (A390.0), which has been used in engine blocks without a liner. An electrochemical surface treatment is used to etch away some of the matrix aluminum so that the eutectic and primary silicon particles provide the bearing surface, resulting in improved wear resistance. Jorstad (Ref 6) has suggested the use of this alloy for other weight-saving applications where good wear resistance is required (for example, brake drums and disk brake rotors).

A powder metallurgy (P/M) production route for the manufacture of cylinder liners from hypereutectic aluminum-silicon alloys has also been explored (Ref 4). Using this method, the size of the primary silicon particles may be optimized and solid graphite can be added to the matrix to serve as a lubricant. The liners are then inserted into the engine block, which is produced from conventional aluminum-base alloys.

While applications for aluminum-silicon alloys are currently centered in the automotive industry (which accounts for greater than 50% of the market), other applications in communications equipment, instrumentation, and small engines appear likely. The hypereutectic alloys are likely to dominate because their wear resistance, combined with low coefficient to thermal expansion (CTE) and fluidity properties, allows thinner wall castings to be manufactured.

Both the Aluminum Association (AA) and the Society of Automotive Engineers (SAE) designations are commonly used to classify aluminum-silicon alloys in the United States.

Metallurgy of Aluminum-Silicon Alloys

Aluminum alloys for wear resistance applications are based on the aluminum-silicon alloy system. This binary system is a simple eutectic alloy system with the eutectic composition at 12.5% Si (Fig. 1). Standard alloys, of course, contain a number of alloying ingredients. Selected commercial alloy compositions are shown in Table 1. Table 2 cross references United States aluminum-silicon compositions with compositions of European and Japanese sources.

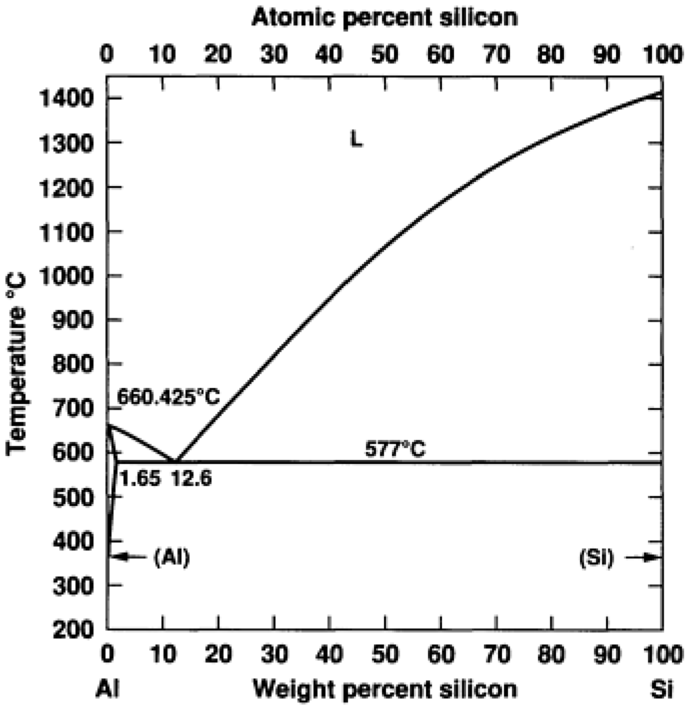

Fig. 1 Aluminum-silicon binary phase diagram. Source: Ref 7

At room temperature, the hypoeutectic alloys consist of the soft, ductile primary aluminum phase and the very hard, brittle silicon phase associated with eutectic reaction. It is this silicon phase that contributes to the very good wear resistance of these alloys. The silicon phase is diamond cubic with a density of ~2.6 g/cm^3 (0.049 lb/in.^{3}) and a Vickers hardness of approximately 10 GPa (1.5 × 10^6 psi). Silicon is essentially insoluble in aluminum (Ref 10). Figure 2 illustrates the typical microstructure of a common hypoeutectic alloy, A357.0. Hypereutectic alloys, the most commonly used wear-resistant alloys, contain coarse, angular, primary silicon particles as well as eutectic silicon. These primary silicon particles impart excellent wear resistance to these alloys. A typical microstructure of an unrefined hypereutectic alloy (A390-type) is shown in Fig. 3.

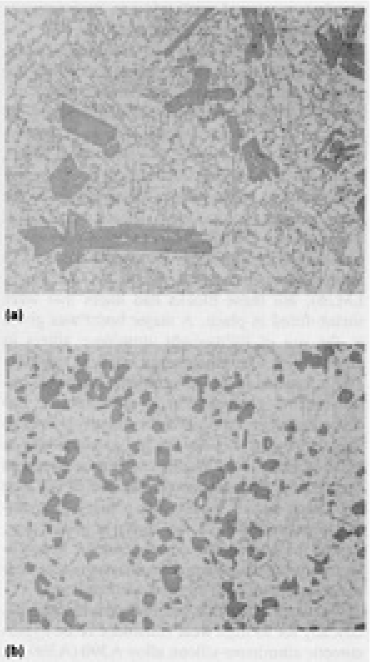

Fig. 3 Microstructure of type A390.0 hypereutectic alloy. (a) Unrefined (Graff-Sargent etch). Dark regions contain coarse primary silicon particles in addition to eutectic silica. (b) Refined (as polished). 120×

Commercial aluminum-silicon alloys (Table 1) generally contain other alloying elements to further enhance or modify the wear resistance or impart additional properties to these alloys.

Iron. The most common alloying element is iron, which can be tolerated up to levels of 1.5 to 2.0% Fe. The presence of iron modifies the silicon phase by introducing several Al-Fe-Si phases. The most common of these are the α and β phases. The α phase has a cubic crystal structure and appears in the microstructure as a "Chinese script" eutectic. The less common β phases generally appear as needles and/or platelets in the structure. Other iron-bearing phases such as Al_6Fe and $FeAl_3$ can also be found in these alloys. Aluminum-silicon alloys intended for die castings typically have higher minimum iron levels to reduce sticking between the mold and the casting.

Magnesium is added to provide strengthening through precipitation of Mg_2Si in the matrix. In an Al-Fe-Si-Mg alloy, the Al-Si-Fe phases will not be affected by the addition of magnesium. However, magnesium can combine with insoluble aluminum-iron phases, resulting in a loss of strengthening potential (Ref 12).

Copper. The most common aluminum wear-resistant alloys also contain copper. Copper additions impart additional strengthening of the matrix through the aging or precipitation-hardening process ($AlCu_2$ or Q phase) or through modification of the hard, brittle Al-Fe-Si phases by substitution in these intermetallic phases. As the strength of these alloys increases through magnesium and copper additions, some sacrifice in ductility and corrosion resistance occurs.

Manganese. Many of the important aluminum-silicon alloys also contain low (<1 wt%), but significant, amounts of manganese. The presence of manganese can reduce the solubility of iron and silicon in aluminum and alter the composition and morphology of the Al-Fe-Si primary constituent phases. For example, manganese additions can favor the formation of constituents such as Al_{12} $(Fe,Mn)_3$ rather than the $Al_9Fe_2Si_2$-type constituents. The manganese-bearing constituents are typically less needlelike or platelike than the manganese-free iron- or (iron/silicon)-bearing primary constituents. Manganese additions also improve elevated-temperature properties of the aluminum-silicon alloys.

Cumulative Effect of Alloying Elements. In summary, aluminum wear-resistant alloys are based on alloys containing the land, brittle silicon phase. Alloying elements such as iron, manganese, and copper increase the volume fraction of the intermetallic silicon-bearing phases, contributing to increased wear resistance compared to binary aluminum-silicon alloys. In addition, magnesium and copper also provide additional strengthening by producing submicroscopic precipitates within the matrix through an age-hardening process.

Properties and Structure

Alloying aluminum with silicon at levels between about 5 and 20% imparts a significant improvement in the casting characteristics relative to other aluminum alloys. As a result, these high-silicon alloys are generally utilized as casting alloys rather than for the manufacture of wrought products. Aluminum-silicon alloys also possess excellent corrosion resistance, machinability, and weldability (Table 3).

Table 3 Relative ratings of aluminum-silicon sand casting and permanent mold casting alloys in terms of castability, corrosion-resistance, machinability, and weldability properties

(a) For ratings of characteristics, 1 is the best and 5 is the poorest of the alloys listed. Individual alloys may have different ratings for other casting processes.

(b) Ability of alloy to withstand stresses from contraction while cooling through hot-short or brittle temperature range.

(c) Ability of molten alloy to flow readily in mold fill thin sections.

(d) Decrease in volume accompanying freezing of alloy and measure of amount of compensating feed metal required in form of risers.

(e) Based on resistance of alloy in standard salt spray test.

(f) Composite rating, based on ease of cutting, chip characteristics, quality of finish, and tool life. In the case of heat-treatable alloys, rating is based on T6 temper. Other tempers, particularly the annealed temper, may have lower ratings.

(g) Based on ability of material to be fusion welded with filler rod of same alloy.

Binary hypoeutectic alloys are too soft to have a good machinability rating. However, the machinability of aluminum-silicon alloys is generally very good in terms of surface finish and chip characteristics. Tool life can be short with

conventional carbide tools, particularly in the case of the hypereutectic alloys. With the recent introduction of diamond cutting tools, tool life has been significantly increased, making the machining of the hypereutectic alloys practical.

Corrosion resistance of these alloys is generally considered excellent. Alloys containing increasing amounts of copper have a somewhat lower corrosion resistance than the copper-free alloys as measured in standard salt spray tests.

Because of their high fluidity and good casting characteristics, these alloys are highly weldable with conventional welding techniques. For joining purposes, brazing alloys and filler wire alloys (for example, alloys 4043 and 4047) (Ref 14) are also based on the aluminum-silicon alloy system.

For wear applications, the important physical properties of these alloys include thermal expansion, thermal conductivity, electrical conductivity, and Young's modulus. Data for these properties are available in standard references (Ref 13, 14, 15, 16, 17, 18). Because silicon is generally in precipitate form, the rule of mixtures is applicable when calculating the properties.

Heat Treatment. Depending on the application, thermal treatments can be employed to:

- Increase strength
- Control thermal growth
- Improve ductility

Aluminum-silicon alloys containing copper and magnesium can be heat treated and aged in the same manner as wrought precipitation-hardened alloys. Depending on the strength level required, room-temperature aging (T4 temper) or elevated-temperature aging (<205 °C, or 400 °F) (T6 temper) may be required after heat treatment to obtain the necessary properties. As the strength of the alloy increases from the T4 to T6 temper, reductions in ductility will occur as the strength increases.

In addition, aluminum-silicon and Al-Si-*X* alloys can be given a higher temperature (205 to 260 °C, or 400 to 500 °F) aging treatment from the as-cast condition to improve their strength and thermal stability. This is particularly important for applications where dimensional tolerances are critical (for example, when the alloy is operated at elevated temperatures as a piston component in an engine). Generally, such an aging practice is designated by the T5 temper.

High-temperature (480 to 540 °C, or 900 to 1000 °F) treatments can also be given to aluminum-silicon and Al-Si-*X* alloys to improve their ductility. These thermal treatments modify the angular primary silicon particles to a more rounded shape. This rounded shape reduces the tendency for crack initiation beginning at the sharp edges of the particles. Such treatments are particularly effective on the hypereutectic alloys. Other means of modifying the shape for improved ductility are discussed in the sections "Modification" and "Refinement" in this article.

Principles of Microstructural Control. The three categories of aluminum-silicon alloys are based on the silicon level (Table 1). These alloy categories are hypoeutectic, eutectic, and hypereutectic. The hypoeutectic alloys solidify with α-aluminum as the primary phase followed by aluminum-silicon eutectic. Other solutes (for example, iron, magnesium, and copper) form phases that separate in the freezing range of the alloy in the interdendritic locations (Fig. 2).

Hypereutectic alloys solidify in a similar manner, but in these alloys silicon is the primary phase rather than α-aluminum (Fig. 3a). The eutectic alloys solidify principally with an aluminum-silicon eutectic structure; either aluminum or silicon is present as a primary phase depending on which side of the eutectic composition (12.7% Si) the alloy lies. A brief description of microstructural control is given below; additional information is available in Ref 2 and 12.

Grain Structure. The grain size of the primary aluminum is controlled through the addition of heterogeneous nuclei to the melt in the form of master alloy inoculants such as Al-6Ti or Al-Ti-B (in the latter, the titanium can range from 3 to 5% and the Ti:B ratio from 3:1 to 25:1). Grain sizes vary from $\sim$100 to 500 μm ($\sim$0.004 to 0.020 in.). An example of the effect of grain refinement by an Al-Ti-B refiner is shown in Fig. 4.

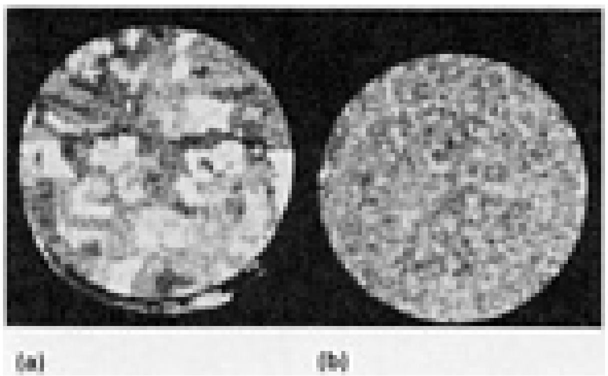

Fig. 4 Effect of grain refinement by the addition of an Al-5Ti-0.2B master alloy to type A356.0. (a) Without titanium addition. (b) With 0.04% Ti addition. Etched with Poulton's reagent. 0.85×

Cell Size. The interdendritic arm spacing (or cell size) is controlled by the cooling rate (Ref 19), which is in turn a function of the casting process and section thickness. The smallest cell size is achieved with thin-wall high-pressure die casting. At the other extreme, thick-wall and castings exhibit the largest dendrite cell size. Casting processes such as low-pressure die casting and permanent mold casting provide intermediate solidification rates and consequently cell sizes that lie between the two extremes. In a similar fashion to the cell size, the constituent phase size is largely controlled by the freezing rate.

Modification. The term modification refers to the change in morphology and spacing of the aluminum-silicon eutectic phase induced by the addition of a chemical agent such as sodium or strontium. There is a change from large divorced silicon particles to a fine coupled aluminum-silicon eutectic structure with an addition of approximately 0.001% Na or 0.005% Sr to the melt. Varying degrees of modification (Fig. 5) are obtained with lower levels of addition. For details of the mechanism and practice of modification, see Granger and Elliott (Ref 12).

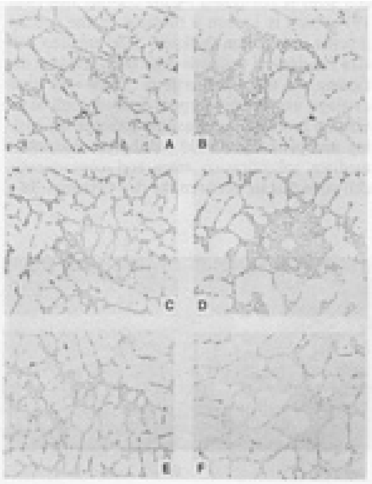

Fig. 5 Variation in microstructure as a function of the degree of modification. The modification level increases from A to F; thus microstructure F is highly modified. Source: Ref 2, 12

Antimony is also used to modify (more accurately, refine) the eutectic structure in hypoeutectic and eutectic alloys, particularly in Europe and Japan. Like sodium and strontium, it increases the fluidity of the alloys and improves mechanical properties. Furthermore, it is permanent, allowing melts to be more effectively degassed, which, in turn, provides sounder castings. The great disadvantage of antimony is that it poisons (or negates) the effect of sodium and strontium, and it also creates a problem in recycling. An additional serious drawback is the potential for the formation of stibine gas, which is highly toxic. Unlike sodium and strontium, which can be used to effectively modify eutectic

structures over a wide range of freezing rates, antimony provides eutectic refinement only at the relatively high rates experienced in die castings and some thin-wall permanent mold castings.

Refinement. In hypereutectic alloys, the primary phase is silicon. In order to provide the desired small well-dispersed silicon particles, phosphorus is added to the level of about 0.1% P through the addition of a master alloy such as Cu-10P. The phosphorus combines with aluminum to form aluminum phosphide, AlP, which provides effective nuclei for the silicon phase much the same as TiB_2-type particles are effective nuclei for α-aluminum (Fig. 3b). However, phosphorus also negates the effectiveness of sodium and strontium. It does so by combining with them to form phosphides, which do not modify the eutectic structure. Similarly, sodium and strontium reduce the effectiveness of phosphorus additions by refining the primary silicon phase.

Gas Porosity. Hydrogen porosity can be controlled by maintaining gas levels at $\leq$0.10 cm^3/100 g. This is not readily accomplished, particularly when modification of the melt is being sought with the addition of sodium or strontium. However, gas fluxing methods are available (Ref 20) that provide the means of reducing hydrogen levels to the desired range.

Also deleterious to casting soundness is the presence of nonmetallic inclusions that act as nuclei for gas pores. Various molten metal filtration systems are available for inclusion removal (Ref 20).

Sludge. A problem experienced with aluminum-silicon alloys is the formation of hard intermetallic phases of the Al(FeM)Si-type, which settle out under gravity from the melt (Fig. 6). The conditions that favor the formation of these phases are low holding temperatures (which are often employed in the die-casting industry); a quiescent melt; and relatively high levels of iron, manganese, and chromium. The relative tendency to form sludge in the holding furnace is given by a segregation factor (SF):

$$SF = (\%Fe) + 2\,(\%Mn) + 3\,(\%Cr) \quad \textbf{(Eq 1)}$$

The relationship among the segregation factor, holding temperature, and sludging tendency is given for alloy AA 339 and several other aluminum-silicon alloys in Ref 21.

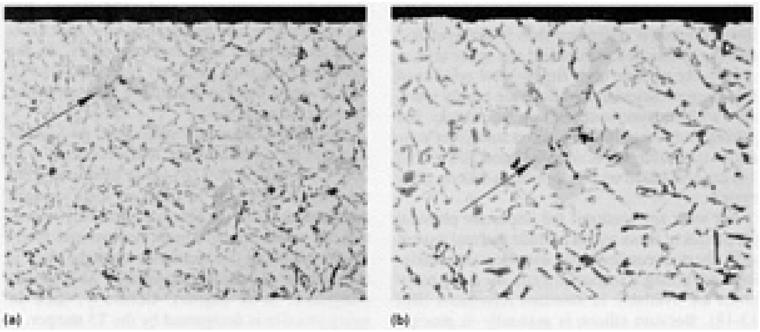

Fig. 6 Coarse intermetallic Al_{12} (Fe,Mn,Cr)$_3$ Si_2 phase constituent generated by entrapped sludge in alloy 339. (a) 130×. (b) 265×

Wear Behavior

The two major types of wear relevant to industrial applications of aluminum-silicon alloys are "abrasive" and "sliding" wear. These have also been identified by Eyre (Ref 3) as the most common types of wear. Wear mechanisms, though, can be thought of as involving more specific descriptions of local processes occurring in the metal and countersurface of the wear system during the wear process. Wear mechanisms are discussed in detail in this Volume in the Sections "Wear by Particles or Fluids," "Wear by Rolling, Sliding, or Impact," and "Chemically Assisted Wear." The purpose of this discussion is to focus on the interaction between microstructure and wear mechanisms. This is important for aluminum-

silicon alloys because of the variety of microstructures that can be achieved as the alloys are processed for particular applications. The relative effects of silicon particles, matrix hardness, and intermetallic constituents on the wear resistance of aluminum-silicon alloys are summarized below.

Silicon Particles. Under relatively light load conditions, which are normally associated with low (<10^{-11} m^3/m) losses, wear resistance is not a strong function of silicon content (Ref 22, 23, 24, 25). In general, however, silicon additions to aluminum will increase the wear resistance. The principal mechanism appears to be the influence of the hard silicon particles, which lead to higher overall levels of hardness. The fact that the hard silicon particles are surrounded by a softer and relatively tough matrix improves the overall toughness of the material and can contribute to wear resistance by favoring more plastic behavior. The eutectic and hypereutectic silicon alloys, with increased volume fractions of hard primary silicon particles relative to the hypoeutectic alloys, might be expected to have the best wear resistance of the aluminum-silicon alloys. Andrews *et al.* (Ref 26, 27), for example, found that increasing the silicon content in hypereutectic alloys reduced wear. However, binary alloy data (Ref 22, 28) indicate that the hypereutectic alloys are not necessarily the most wear resistant. Clarke and Sarkar (Ref 28) found that there was a relative minimum in wear for binary aluminum-silicon alloys at about the eutectic level, as did Jasim *et al.* (Ref 22), especially at applied pressures <100 kPa (<15 psi). Clarke and Sarkar attribute the effects of silicon in part to its effect on metal transfer mechanisms between the pin and countersurface (Ref 29). There is also evidence for increased wear resistance with refinement of the silicon particle morphology (Ref 30, 31).

It is clear, therefore, that microstructure-based explanations are needed to account for the variation in wear rates with silicon content. Moreover, there is a need to account for the reduction in strength that occurs with increased silicon content (Ref 32, 33). The complex effects of composition on wear behavior suggest that wear resistance depends on other material properties (for example, fracture toughness) (Ref 34). Thus lower fracture toughness at higher levels of silicon could lead to higher wear rates if larger pieces of debris are created during the wear process. Variations in toughness and strength with composition might also account for the apparent ability of the near-eutectic compositions to have a greater load-bearing capability at a given wear rate than either higher or lower silicon levels.

Matrix Hardness. Increased matrix hardness is typically achieved through the heat treatment response produced by copper and magnesium additions. Most commercial applications of aluminum-silicon alloys, in fact, depend on the increased strength achieved by heat treatment. The improved wear resistance of precipitation-strengthened material compared to solid solution strengthened material under low wear conditions was also noted by Soderberg *et al.* (Ref 35) using aluminum alloy 6061, which is strengthened primarily by Mg_2 Si precipitates. This is also the strengthening mechanism in the heat-treatable magnesium-bearing aluminum-silicon alloys. Although heat treatment has a beneficial effect (Ref 26, 27, 32), variations in matrix hardness may be less important than the effects of silicon content (Ref 27).

Intermetallic Constituents. In addition, there are important "other" hard phases present in commercial aluminum-silicon alloys that provide enhanced wear resistance. These constituents (for example, Al-Fe-Si, Al-Fe-Mn, Al-Ni, Al-Ni-Fe, Al-Cu-Mg) have varying degrees of hardness (Ref 36, 37, 38). Despite the apparent scatter, these constituents are all much harder than the aluminum matrix. Some examples of the hardness values of these intermetallic compounds are shown in Table 4.

Table 4 Typical hardness values of selected intermetallic constituents of aluminum-silicon alloys

Phase	Hardness		Ref
	MPa	**kfg/mm²**

Typical room-temperature hardness values for the aluminum alloy matrices would be <1000 MPa (<100 kgf/mm^2). The hardness values of the intermetallics decrease with increasing temperature (Ref 36), albeit at slower rates than the matrix hardness.

The addition of "hard" phases in the form of particles or fibers to reduce wear is also utilized to create metal-matrix composites (MMC) materials (Ref 39). These materials utilize hard intermetallic, cermet, or ceramic phases to provide the high hardness material for wear resistance. Hornbogen (Ref 40) and Zum Gahr (Ref 41) have described in quantitative terms how the contribution of these hard phases to wear resistance can be modeled in terms of their volume fraction and morphology. This composite approach has been effectively used to develop new piston materials (see the section "Metal-Matrix Composites" in this article).

Finally, the use of "softer" constituents (for example, graphite) should also be noted as an active area for development of wear-resistant aluminum-silicon MMC materials (Ref 32, 39, 42). In these materials, ranking may depend on whether volumetric wear rates (in units of m^3/m) or seizure resistance is being considered. The presence of the softer phase may lead to greater volumetric wear in some cases but greater resistance to seizure (higher load at seizure) in other cases.

To summarize, the results of wear studies using aluminum-silicon alloys illustrate a variety of mechanisms. The effect of variations in silicon particle morphology is often not clear cut, although heat treatment is beneficial to the sliding wear resistance. Therefore, selection of an optimum microstructure is often difficult in practical situations where several wear types or mechanisms could occur. In general, either eutectic or hypereutectic alloys offer the greatest wear resistance under a wide range of wear conditions. Selection may then hinge on the dependence of in-service performance on other alloy characteristics or cost. Overall, the aluminum-silicon alloy system provides a good basis for developing lightweight, strong, wear-resistant materials. Examples of these applications will be discussed in the following sections.

Aluminum-Silicon Alloy Applications

Aluminum-silicon alloys are used in a variety of automotive, aerospace, and consumer product applications.

Automotive Components

Table 5 lists typical automotive components made from aluminum-silicon casting alloys (Ref 43). The eutectic or nearly eutectic alloys (for example, 332, 336, and 339) (Ref 44), are perhaps the most widely used. Equivalent versions of these alloys are used for similar applications by European and Japanese automakers (Ref 45, 46, 47).

Table 5 Automotive engine applications of aluminum-silicon alloys

SAE alloy	Type of casting[a]	Typical application
319.0	S	General purpose alloy
332.0	PM	Compressor pistons
333.0	PM	General purpose
336.0	PM	Piston alloy (low expansion)
339.0	PM	Piston alloy
355.0	S, PM	Pump bodies, cylinder heads
390.0	D	Cylinder blocks, transmission pump and air compressor housings, small engine crankcase, air conditioner pistons
A390.0	S, PM	Cylinder blocks, transmission pump and air compressor housing, small engine crankcase, air conditioner pistons

(a) S, sand cast; D, die cast; PM, permanent mold.

Pistons. Typical applications for aluminum-silicon alloys in the French automotive industry are shown in Table 6 (Ref 45). In addition to being cast, the A-S12UN (eutectic) alloy can also be forged (Ref 48). Similarly, AA 4032, somewhat

similar in composition to 336, is also widely used as a piston alloy (for example, for high-performance forged pistons). Hypereutectic alloys are also used for cast pistons, especially in diesel engines (Ref 45, 49). The potential benefit from composites that combine the strength reinforcement of ceramics with an aluminum-silicon alloy matrix has also been evaluated (Ref 45, 47, 48).

Table 6 Selected aluminum-silicon alloy applications in automobiles produced in France according to engine type and specific automobile manufacturer

	. . .	A-S13UN	. . .	. . .

(a) F, cast iron liner.

(b) A, aluminum block.

Engine Blocks and Cylinder Liners. The evolution of lightweight power plants has depended not only on lightweight pistons but also on the availability of wear-resistant cylinder liners and engine blocks. Hypereutectic liners were described by Mazodier (Ref 50) and El Haik (Ref 51). It was also known that hypereutectic aluminum-silicon alloys had excellent properties for engine blocks (Ref 52, 53, 54). This led to the development and application, in both the United States and Europe, of the A390 (A-S17U4) alloys for die cast engines (Ref 55, 56, 57, 58, 59, 60). An important aspect of the A390 success is the use of a "system" (Ref 60) that includes the engine alloy, the piston materials (electroplated cast F332[AA 332.0] alloy), and the cylinder bore finishing process. Fine honing to a 0.075 to 0.15 μm (3 to 6 μin.) surface finish, followed by controlled etching/polishing to leave silicon particles standing slightly above the alloy surface, was deemed necessary for optimum wear resistance.

Efforts to simplify the 390-type technology by finding a more wear-resistant alloy for the cylinder or reducing the difficulties of finishing the bore have led to substitute alloys. One approach has been the use of a lower silicon alloy containing more nickel and manganese (for example, the Australian-3HA alloy, with a nominal composition of Al-13.5Si-0.5Fe-0.45Mn-0.5Mg-2Ni) (Ref 61).

Continuing interest in the use of more highly wear-resistant materials in other engine-related parts has led to recent applications such as roller-type valve rocker arms (Ref 62) and valve lifters for the Toyota Lexus (Ref 63, 64). The rocker arm alloy used in the Mazda 929 is a nominal Al-10Si-2.7Cu-0.8Mg-0.45Mn alloy somewhat similar to the AA 383 alloy. The valve lifter, on the other hand, is a strontium-modified Al-Si-Cu alloy designated 4T12 (composition, Al-10.5Si-4.5Cu-0.6Mg-0.2Mn).

Typical examples from a more detailed compilation of aluminum alloys used in wear-resistant applications in U.S. autos are shown in Table 7.

Table 7 Wear-resistant aluminum-silicon alloys used in automotive piston components produced for United States automotive manufacturers in 1978 to 1985 model years

Application	Manufacturer	Model/make	Model year(s)
Internal combustion engine components			
Pistons	American Motors	All	1978-85
	Ford	Mercury	1978-81, 83-85
	General Motors	Buick	1978-81, 84-85

Bearing Alloy Components. Aluminum alloys have been utilized for bearing applications for many years. The many uses range from diesel and internal combustion engines to a variety of tooling applications (for example, presses, lathes, and milling machines) (Ref 66). Important cast bearing alloys were based on aluminum-silicon or Al-Sn-Cu alloys, whereas wrought bearing alloys have included the 8*xxx* types (for example, AA 8081 and AA 8020) (Ref 66, 67). Compositions of various aluminum bearing alloys are listed in Table 8.

Table 8 Nominal compositions of standard aluminum-silicon alloys used in bearing applications

Improved strength and fatigue performance, as well as some increased wear resistance, has been achieved with silicon additions. Thus, alloys SAE 780 and SAE 781 have become widely used for automotive applications such as main and connecting rod bearings (Ref 68, 69). The higher silicon alloy, 781, is also used in bushings and thrust bearings. Its improved wear performance has been attributed to the increased silicon content of the wear surface (Ref 70). These aluminum-silicon alloys are readily used with steel backing in high-load situations.

Advanced Aluminum Bearing Alloys. The nominal compositions of improved bearing alloys with silicon additions are listed in Table 9.

Table 9 Nominal compositions of advanced aluminum-silicon alloys used in bearing applications

Alloy[(a)]	Composition, wt%						Ref
	Si	**Sn**	**Cu**	**Mg**	**Pb**	**Other**

(a) Arbitrary designations

Although a soft phase (for example, tin) is normally considered desirable for avoiding seizure, the compatibility of an Al-11Si-1Cu alloy was better than that of the traditional aluminum-tin alloy (SAE 783) (Ref 71). The silicon-copper alloy also had much better fatigue resistance. The improved properties resulted in applications such as diesel crankshaft and connecting rod bearings. Nevertheless, in line with the concerns expressed by Davies (Ref 72), the harder silicon-containing alloy was more sensitive to misalignment-induced seizure.

The addition of silicon to aluminum-tin alloys containing lower tin levels than that of the 783 alloy provided a compromise between the conformability of the soft-phase material and the benefits of the harder silicon phase for improved wear and fatigue resistance (Ref 73). This alloy could apparently be used without the common lead alloy overlays employed for seizure resistance. The importance of fatigue resistance was also emphasized in the improved Al-Sn-Si alloys reported by Ogita *et al.* (Ref 74). As shown in Table 9, these alloys are somewhat similar to those of Fukuoka *et al.* (Ref 73).

As another alternative to the lead- or tin-containing alloys, a graphite-containing Al-12Si alloy has been successfully evaluated for bearings (Ref 75). The use of a modified lead plus indium addition to an Al-11Si-Pb bearing alloy has also been reported (Ref 76).

Japanese concerns with the pollution and toxicity aspects of cadmium-containing alloys have led to improved aluminum-zinc bearing alloys (Ref 77). These have also been improved with silicon additions. The additional matrix wear between the silicon particles is believed to create lubricant reservoirs that enhance seizure resistance. However, overlays (lead-tin alloys) are still required for best conformability.

Finally, the combined effect of silicon and refinement of the silicon- and lead-bearing phases by rapid solidification processing has resulted in an improved Al-6Pb-4Si bearing alloy (Ref 78). This alloy has grown in usage recently and is projected to be used in 78% of the cars built in the United States during 1991.

Because of the increasing understanding of the balance among wear, fatigue, and seizure resistance of bearing materials, silicon alloys have been used to develop new and improved bearing materials. Further improvements will undoubtedly be necessary as engine operating conditions evolve toward higher temperatures and operating speeds.

Consumer Electronics Components

The growth of this market, which encompasses video cassette recorders (VCRs), video tape recorders (VTRs), digital audio tape (DAT) applications, and other devices (for example, personal computers), has created numerous opportunities for the use of lightweight, relatively corrosion-resistant and wear-resistant aluminum-silicon alloys. VTR cylinders are specifically cited by various Japanese authors (Ref 79, 80, 81) because the eutectic-type silicon alloys have low coefficients of friction against the tape.

Aerospace Components

A nonautomotive engine application of aluminum-silicon alloys is the use of the 390-type alloys in an aircraft engine (the Thunder engine) (Ref 82).

Breakthroughs in Aluminum-Silicon Wear-Resistant Materials

Metal-Matrix Composites. Composite pistons were recognized early as a potentially viable application of MMC technology. While some composite approaches, especially for the severe operating conditions of diesel pistons, recommended the addition of specific metallic inserts to achieve improved performance (Ref 83), the bulk of development efforts have gone into the incorporation of ceramic fibers.

The use of ceramic fiber aluminum-silicon MMC materials for pistons is described in a variety of publications (Ref 47, 48, 84, 85, 86, 87, 88). There are clear benefits to strength at elevated temperatures and reduction of the thermal expansion coefficient. These materials appear to be especially applicable in critical areas such as the top piston rings and

top land (a high-temperature area). The castability of the aluminum-silicon alloys is a favorable factor in their use as matrices, particularly because squeeze casting is one of the preferred fabrication routes for composite pistons.

The property improvements at elevated temperatures have encouraged ongoing development of the MMC technology for automotive engine applications, including engine blocks. The ability of the MMC approach to allow selective strengthening of the cylinder region was taken advantage of by Honda engineers (Ref 89), who utilized composite reinforcement of alloy ADC12 (a Japanese alloy similar to 383)in the manufacture of a die cast engine block.

Powder Metallurgy. The combined benefits of high silicon content and refined silicon particle size on wear resistance are strong driving forces behind the use of P/M techniques for making aluminum-silicon alloy parts. The P/M approach has been of special benefit to the hypereutectic silicon alloys. One example of this is the use of P/M A-S17U4 alloy to make cylinder liners (Ref 90, 91). The properties of these alloys exceed those of standard alloys (Ref 92). In addition, high levels of additional elements can be utilized to obtain good strength and wear-resistant properties at elevated temperatures (Ref 93, 94, 95).

The refined microstructures available from the P/M fabrication of hypereutectic alloys have a beneficial effect on fatigue characteristics as well. This attribute has been utilized in the production of rotors and vanes for rotary automotive air conditioners (Ref 96). For this application, P/M alloys with high levels of iron or nickel are blended with P/M 2024-type alloys to create alloys containing 17 to 20% Si and 5 to 8% Fe or Ni.

Spray casting, as exemplified by Osprey processing, has been shown to offer benefits similar to powder metallurgy (Ref 97, 98). This has the potential for even greater cost savings, which is an important factor if the aluminum industry is to compete successfully in the automotive market. In a comparison of the structure in an Al-20Si alloy, Kahl and Leupp (Ref 97) showed that there was practically no difference in silicon particle size between the P/M and Osprey processing routes. Furthermore, they claimed the the fine and uniform silicon particle size resulted in improved wear behavior compared with that of conventionally produced material, although details of their test procedure are not know. Earlier work at Delft University (Ref 99) compared the rate of mass loss of an Al-20Si-3Cu-1.3Mg alloy rubbing against cast iron at pressure level of 5.5 MPa (800 psi). In this test, the Osprey material showed better resistance to wear than either the ingot metallurgy (I/M) or P/M samples. The reason for the better performance of the Osprey product compared with the P/M material was not clear, but it was hypothesized that the slightly larger silicon particles of the Osprey product helped reduce the fretting wear.

Coatings/Surface Treatments. Other approaches to the wear (adhesion) problems of aluminum pistons moving in aluminum cylinders have taken the path of coating or surface treatment of the piston rings and cylinder bore to minimize wear problems (Ref 100). The selective fiber strengthening noted above is related to this problem also. One widely used treatment is the so-called Nikasil treatment (Ref 101), an electrochemical treatment utilizing a dispersion of silicon carbide particles, preferably <4 μm (<160 μin.) in size, in a nickel matrix.

Efforts to take advantage of both the P/M and surface treatment approach are exemplified by the emerging surface treatment technologies of surface alloying via ion implantation (Ref 102, 103, 104, 105), thermal spraying (Ref 106, 107, 108), and surface treating or alloying using laser treatments (Ref 109, 110, 111). Ion implantation is recognized for its ability to impart wear-resistant surfaces, but principal applications have been to protect tool surfaces in critical processing operations. Laser hardening can be achieved through laser cladding to produce a chemically different surface or through the effective heat treatment (or remelting and rapid solidification) brought about by laser heating. The work by Blank *et al.* (Ref 111) using 7 and 12% Si alloys, however, indicated that surface alloying (for example, with iron or iron plus vanadium) was more effective for increased wear than surface heat treatment effects alone. In any case, the ability to tailor surface properties to a technological need will enable engineers to obtain further enhancement of the wear resistance of the aluminum-silicon base alloys without sacrificing their other advantages.

Friction and Wear of Cemented Carbides

Henry J. Scussel, GTE Valenite

Introduction

CEMENTED CARBIDES, best known for their superior wear resistance, have a range of industrial uses more diverse than that of any other powder metallurgy product. Common uses include metalworking tools, mining tools, and wear-resistant components. All of these applications have one physical property requirement in common: the ability to resist wear. The variety of wear mechanisms encountered in service requires the use of a number of carbide grades with different chemical and metallurgical properties.

This article will discuss the raw materials used in the production of cemented carbides; the manufacturing methods employed; their physical, mechanical, and thermal properties; and the wear mechanisms encountered in service. Emphasis is placed on tungsten carbide-cobalt (WC-Co) or tungsten carbide-nickel (WC-Ni) materials as used in nonmachining applications.

Raw Materials

The unique character of cemented carbides begins with the raw materials utilized in their manufacture. Table 1 lists the basic physical and mechanical properties of commonly used carbide and metallic binder materials. A more complete discussion of raw materials can be found in the article "Cemented Carbides" in *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials,* Volume 2 of *ASM Handbook* (1990).

Co	<100	Cubic/hexagonal	1495	2725	8.9	207	30.0	16.0
Ni	<100	Cubic	1455	2650	8.9	207	30.0	15.0

Tungsten carbide (WC) is manufactured through the reduction of tungsten oxide and subsequent carburization at 1400 to 1500 °C (2550 to 2730 °F). Particle sizes range from 0.5 to 30 μm. Each particle is composed of numerous tungsten carbide crystals. The tungsten powder is sometimes doped with small (<1 wt%) amounts of vanadium, chromium, or tantalum/niobium before carburization. These materials act as grain-growth inhibitors, particularly in the very fine (<1 μm) particle sizes.

Cobalt (Co) is the most widely used binder in WC-base hardmetals. Cobalt is the preferred binder due to its outstanding wetting and adhesion characteristics. As shown in Table 1, cobalt has a low-temperature hexagonal phase and as high-temperature cubic phase, with a phase transition at about 415 °C (780 °F). Cobalt is manufactured through reduction of cobalt oxides or derived from organic salts--particularly cobalt oxalate. The cobalt binder phase is altered significantly during milling with WC and subsequent liquid-phase sintering operations.

Nickel (Ni) is used as a binder in less than 10% of total carbide production because of poor WC wettability, which results in decreased hardness and toughness relative to cobalt grades at identical binder levels. Tungsten carbide-nickel grades offer slightly improved corrosion and oxidation resistance over cobalt binder grades.

Tantalum/titanium/niobium carbides (TaC/TiC/NbC) are used predominately in metal forming applications when metal pick up or galling of dies is problem. Tantalum carbide, in particular, is used in small quantities (<1 wt%) as a grain-growth inhibitor, and in fairly large amounts (>6 wt%) to provide increased hot hardness in metal cutting.

Chromium carbide is added to both WC-Co and WC-Ni grades is small quantities (<5 wt%) to improve corrosion and oxidation resistance. The WC-Ni grades alloy with chromium or chromium carbide have shown significantly improved corrosion resistance over conventional WC-Co or WC-Ni grades. Chromium or chromium carbide additions increase the tendency to from a brittle carbon-deficient ηphase, which can result in decreased strength and toughness.

Manufacturing Methods

Grade Powders are produced by combining WC with cobalt or nickel binder and, depending on the application, varying amounts of TaC/TiC/NbC. The grade powder is milled in conventional ball mills, attritor mills, or vibratory mills. The milling process reduces the particle size of the raw materials and also provides uniformity of mixture. Milling operations are typically carried out in a protective solvent such as alcohol, used to minimize heating and subsequent oxidation of the powder, and to disperse the powder particles to achieve intimate mixing. During the grade powder manufacturing process, 2 to 3 wt% of a solid lubricant such as paraffin wax is added. This lubricant reduces the potential for oxidation and provides green strength to as-pressed components. The lubricant/solvent/powder slurry is then dried to remove the solvent. Spray drying is the most widely used atomized through a nozzle and sprayed into a stream of nitrogen gas. The solvent is vaporized, condensed outside the chamber, and reused. The dried powder is now in the form of free-flowing spherical aggregates on the order of 150 to 250 μm in diameter (Fig. 1).

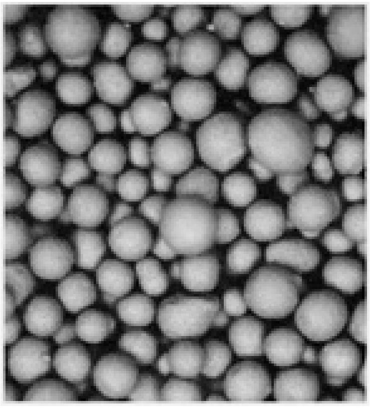

Fig. 1 Spray-dried cemented carbide powder. 40×

Pressing or powder consolidation processes include a number of vastly different techniques. Many wear components are produced on automatic or semiautomatic presses at pressures of 50 to 150 MPa (7 to 22 ksi). Press tooling typically consists of carbide dies, punches, and core rods to minimize wear. In cold isostatic pressing, the grade powder is consolidated into a rough billet or ingot using equal pressure from all directions. This rough billet is then preformed or machined to a net shape. Extrusion of carbide grade powders is used to produce long components of small, constant cross section. Higher lubricant levels ad different lubricant types are used in extrusion. There has been limited injection molding of cemented carbides.

Preforming or shaping operations are used to machine components to a net shape using abrasive (diamond) grinding wheels or single-point diamond tools. These operations are used when the final part cannot be pressed to its final shape, or the production quantity is too low to justify te investment in press tooling.

Sintering operations are carried out in batch-type or semicontinuous furnaces in either a vacuum hydrogen, or other inert atmosphere. A 400 to 500 °C (750 to 930 °F) hold dewaxes the parts, and the vaporized lubricant is condensed outside the heating chamber and discarded. Final sintering takes place at 1300 to 1600 °C (2370 to 2910 °F); the precise temperature depends on the cobalt content--the grades with the higher cobalt contents have the lower sintering temperatures. This final sintering temperature is above the eutectic temperature of the carbide-binder system, and the binder partially melts. The excellent wettability of WC by cobalt results in rapid liquid-phase sintering, which promotes coalescence of the WC particles and produces a fully dense, virtually porosity-free microstructure. Linear shrinkage on the order of 15 to 25% takes place.

The advantages of hot isostatic pressing (HIP) have been exploited since the early 1970s. Components requiring high reliability and/or surface integrity are HIPed to eliminate residual porosity, pits, or flaws. Materials are heated to a temperature above the liquidus, and the vessel is pressurized with an inert gas to sightly less than 100 MPa (15 ksi). The combination of pressure and temperature forces the binder into any residual pits or porosity. The result is porefree component with higher reliability. Recent advances have combined liquid-phase sintering and HIP into a single sinter-HIP process. Sinter-HIP uses lower pressures and higher temperatures than conventional HIP with no sacrifice in component reliability. The resulting sinter-HIP microstructure is more uniform than that produced by conventional HIP, and sinter-HIP is more cost effective (Ref 1).

Finishing operations include grinding with diamond wheels, electrical discharge machining (EDM) using wire or shaped electrode, and edge honing using a variety of abrasive techniques. Final lapping to mirrorlike finishes is accomplished using diamond-containing slurries or pastes.

Physical or chemical vapor deposition (PVD or CVD) are now used on the majority of metal cutting inserts and on some wear parts. The coatings are on the order of 5 μm thick and consist of titanium carbide (TiC), titanium nitride (TiN), aluminum oxide (Al_2O_3), or a combination thereof. Their purpose is to minimize the wear process during steel machining; in particular, to minimize the dissolution of the workpiece material into the cutting tool. Titanium nitride coatings are also purported to reduce the frictional forces at the tool/workpiece interface.

The methods of application for CVD and PVD coatings differ substantially. The CVD coatings are applied at temperatures of about 1000 °C (1830 °F), and as a result contain higher levels of residual stresses due to the difference in both thermal expansion coefficients and elastic moduli between the substrate and the coating. This results in a significant decrease (30%) in three-point bending strength of coated parts compared to uncoated parts. The PVD process is applied at less than 500 °C (930 °F) and results in reduced stresses in the coating and minimizes any loss in strength. Coatings applied by PVD or CVD do not have the same utility in nonmachining applications where high-temperature wear resistance is not required. Coatings may provide some improvement in corrosion resistance or resistance against smearing or pickup of the workpiece onto a forming tool.

Properties

The properties of cemented carbide grades are predominately determined by their chemical composition and the grain size of the tungsten carbide in the sintered part. Table 2 summarizes the properties of some typical carbide grades used in wear part application. Table 3 relates these compositions to application areas.

Table 2 Properties of representative cobalt-bonded cemented carbide grades

Nominal composition	Grain size	Hardness, HRA	Density, g/cm^3	Transverse strength		Compressive strength		Modulus of elasticity		Relative abrasion resistance[(a)]	Coefficient of thermal expansion, μm/m · K		Thermal conductivity, W/m · K
				MPa	ksi	MPa	ksi	GPa	10^6 psi		at 200 °C (390 °F)	at 1000 °C (1830 °F)

(a) Based on a value of 100 for the most abrasion-resistant material

Table 3 Nominal composition and properties of representative cemented carbide grades and their applications

Typical application	Binder content, wt%	Grain size	Hardness, HRA
Heavy blanking punches and dies, cold heading dies	20-30	Medium	85
Heading dies (severe impact), hot forming dies, swaging dies	11-25	Medium to coarse	84
Back extrusion punches, hot forming punches	11-15	Medium	88
Back extrusion punches, blanking punches and dies for high shear strength steel	10-12	Fine to medium	89
Powder compacting dies, Sendzimir rolls, strip flattening rolls, wire flattening rolls	6	Fine	92
Extrusion dies (low impact), light blanking dies	10-12	Fine to medium	90
Extrusion dies (medium impact), blanking dies, slitters	12-16	Medium	88
Corrosion-resistant grades, valves and nozzles, rotary seals, bearings	6-12	Fine to medium	92
Corrosion-resistant grade with good impact resistance for valves and nozzles, rotary seals and bearings	6-10 Ni	Medium	90
Deep draw dies (nongalling), tube sizing mandrels	10 Co with TiC and TaC	Medium	91

Hardness is typically measured on the Rockwell A scale with values ranging from 83.0 HRA for high-cobalt coarse-grain grades, to 93.0 HRA for low-cobalt fine-grain grades. Vickers diamond pyramid hardness (HV) is widely used in Europe; values range from 800 to 2000 kg/mm^2 using a 30 kg load. The precision and accuracy of hardness testing is influenced significantly by the surface finish of the testpiece, parallelism between top and bottom surfaces, and the quality of hardness standards and diamond penetrators. For straight WC-Co grades (those not containing TiC, TaC, or similar additions) with comparable WC grain size, hardness decreases with increasing binder content. Figure 2(a) illustrates the relationship between hardness and cobalt content/WC grain size.

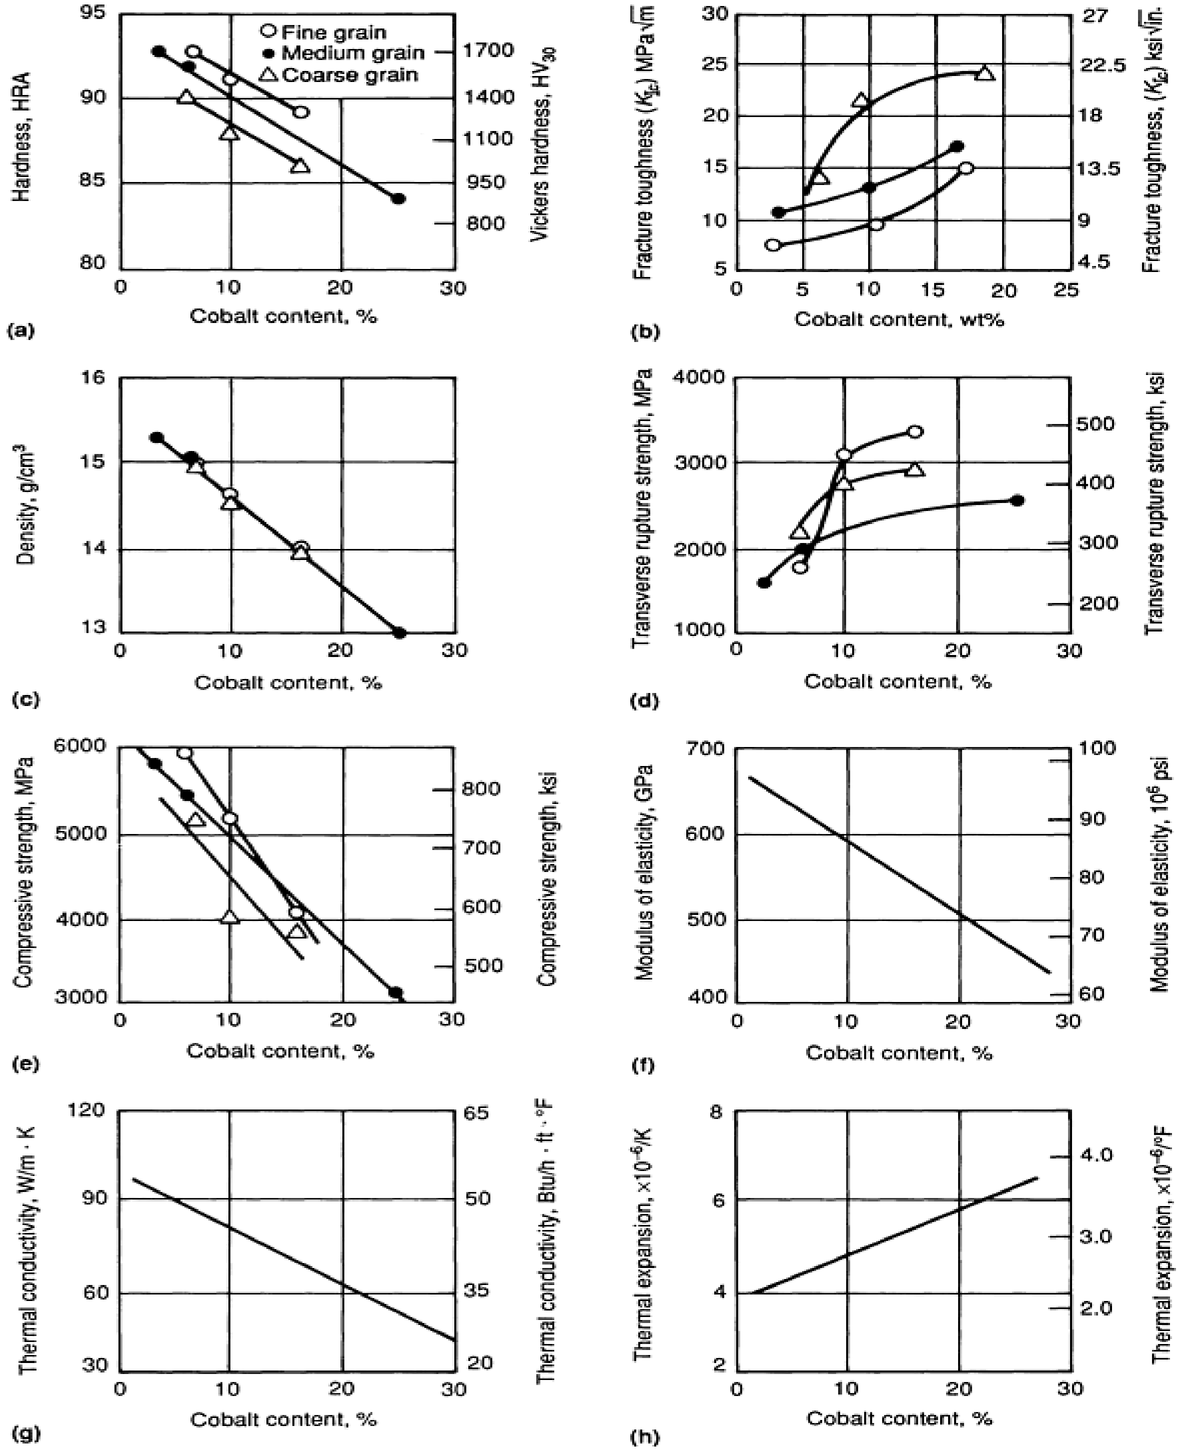

Fig. 2 Variation of properties with cobalt content and grain size for unalloyed grades of cemented carbide

Fracture toughness (K_{Ic}) values indicate the resistance of a material to fracture from intrinsic flaws. A variety of test methods and specimen geometries are used, so caution must be exercised when comparing reported values from different manufacturers. Fracture toughness increases with both increased cobalt content or WC grain size, as shown in Fig. 2(b).

Density varies inversely with cobalt content, as shown in Fig. 2(c). Porosity levels also influence density. Cemented carbide grades used in ferrous alloy machining applications contain higher amounts of TiC/TaC and have density values from 10 to 14 g/cm^3.

Transverse rupture strength (TRS), or three-point bending strength, is the most common method of determining the fracture strength of cemented carbides. Rectangular samples(5 × 6 × 19 mm, or 0.2 × 0.25 × 0.75 in.) are loaded as shown in Fig. 3. The TRS is then calculated using:

$$\text{TRS} = \frac{3FL}{WH^2}$$

where F is the load at fracture, L is the span between supports, and W and H are the width and height of the test bar, respectively. The test itself is sensitive to test bar size (several variations are in use), surface finish, and other test parameters. The response of TRS to cobalt content and tungsten carbide grain size is shown in Fig. 2(d).

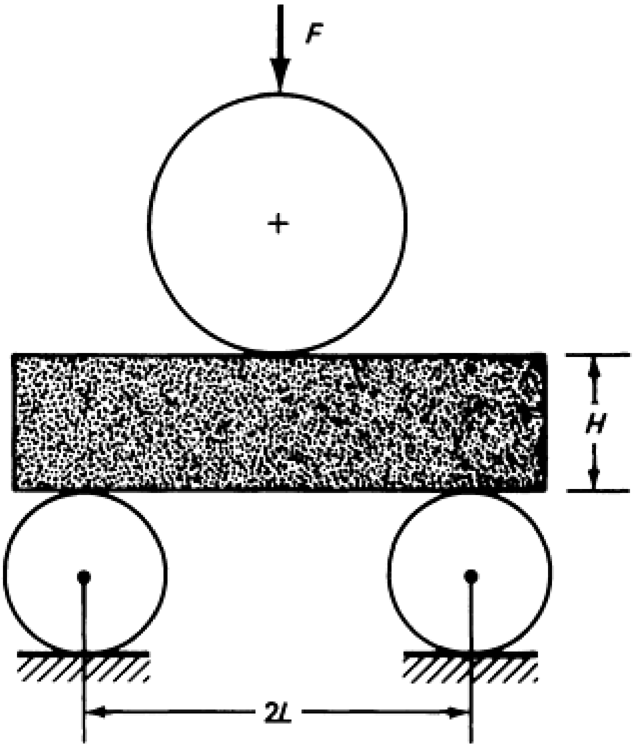

Fig. 3 Schematic of transverse rupture strength testing (three-point bending)

Compressive strength of cemented carbides is greater than that of almost any group of materials, metallic or nonmetallic. Uniaxial compressive strength tests are performed using straight cylindrical samples, a cylinder with reduced diameter at the center of the part to localize fracture, or a straight cylinder held within a sleeve. Reported compressive strength values can vary significantly depending on the size and geometry of the test specimen. Compressive strength varies inversely with cobalt content, and for a given cobalt content, finer grain sizes give the highest value. Figure 2(e) summarizes this compressive strength versus cobalt content/grain size relationship.

Modulus of elasticity, or Young's modulus, also varies inversely with cobalt content (Fig. 2f), but is independent of WC grain size (Ref 2). The elastic modulus of WC is higher than that of any other commercially available material except diamond and cubic boron nitride. As a result, WC-Co alloys have elastic moduli 2 to 3 times those of cast irons or steels.

Elastic modulus measurements are carried out using either mechanical or sonic methods. Mechanical methods involve loading a WC-Co beam and measuring the amount of deflection. Sonic methods are more widely used and utilize resonant vibration of a cylindrical or square rod. The resonant frequency depends on the dimensions of the testpiece, the density of the material, and the elastic modulus of the material.

Thermal conductivity of WC-Co alloys is important in machining applications because the ability of the tool to conduct heat away from the tool/workpiece interface has a definite effect on tool performance. In nonmachining applications, such as a rotary mechanical-pump seal, the tungsten carbide seal ring must have high thermal conductivity to ensure heat flow away from the rotary seal/stationary seal interface. Thermal conductivity decreases with increasing cobalt content and is unaffected by WC grain size (Ref 3), as illustrated in Fig. 2(g). The additional of TiC reduces the thermal conductivity significantly.

Coefficients of thermal expansion are an important design consideration when using WC-Co materials. The linear coefficient of thermal expansion of WC-Co increases with increasing cobalt content (Fig. 2h), and is independent of grain size. Typical low-carbon steels, tool steels, and stainless have thermal expansion coefficients 2 to 3 times greater than those of carbides. In metal forming applications at elevated temperatures, such as warm forming or extrusion, this difference, must be taken into consideration when designing steel/carbide assemblies. This expansion coefficient mismatch also complicates brazing operations when joining cemented carbides to metals.

Porosity in carbides is typically less than 0.1 vol%. ASTM procedure B 276 classifies porosity into three types:

- A-type: pores less than 10 μm in diameter
- B-type: pores between 10 and 25 μm in diameter
- C-type: porosity caused by the presence of uncombined carbon

Porosity is evaluated by observing a polished, unetched surface, and comparing it with standards supplied in the ASTM procedure.

Microstructures for nine typical WC-Co grades are shown in Fig. 4. The microstructures are characterized by the angular, sharp WC grains surrounded by the cobalt binder. Tungsten carbide grain sizes as shown in Fig. 4 vary from <1 μm in the fine grain sizes to 8 to 10 μm in the coarse grain size grades. Microstructures of grades for use as cutting tools and anomalies such as graphite and the carbon-deficient η phase are illustrated in the article "Cemented Carbides" in *Properties and Selection: Nonferrous Alloys and Special-Purpose Materials,* Volume 2 of *ASM Handbook* (1990).

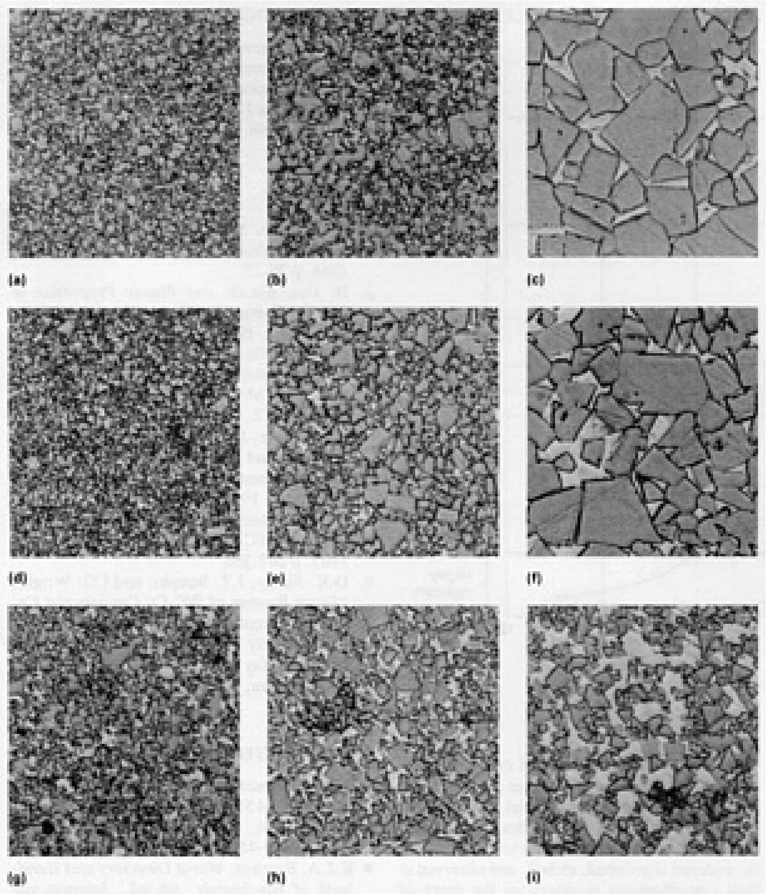

Fig. 4 Cemented carbide microstructures. (a) 94WC-6Co, fine grain size. (b) 94WC-6Co, medium grain size. (c) 93WC-7Co, coarse grain size. (d) 90WC-10Co, fine grain size. (e) 90WC-10Co, medium grain size. (f) 90WC-10Co, coarse grain size. (g) 84WC-16Co, fine grain size. (h) 84WC-16Co, medium grain size. (i) 75WC-25Co, medium grain size. All at 1500×, 3 min etch

Wear Properties of Cemented Carbides

Superior abrasive wear resistance is probably the major reason for the selection of cemented carbides in a wide variety of industrial applications. This superior wear resistance can generally be attributed to their unique composition, which consists of 80 to 95% hard, wear-resistant, fine WC grains combined with a cobalt binder that provides a small amount of ductility to the material. Studies of carbides have shown that abrasive wear involves rounding, fragmentation, and pullout of the WC grains, and subsequent removal of the soft binder phase (Ref 4, 5).

ASTM test B 611 specifies a method for determining the abrasive wear resistance of carbides. In this test, a rectangular carbide testpiece is held against a rotating wheel (either steel or rubber) for a fixed number of revolutions. The test is run either wet or dry. A schematic of the test apparatus is shown in Fig. 5. A steady stream of 30 mesh alumina sand is introduced directly into the carbide/wheel interface. The volume of the testpiece (measured in cubic centimeters) is determined both before the test, and after the predetermined number of revolutions. The volume loss is inversely related to the wear resistance. Typical volume losses for low-cobalt, fine-grain materials is on the order of 3 mm^3. A D2 tool steel is often used as reference material in this test and exhibits a volume loss of 40 to 45 mm^3. Materials are ranked using either the reciprocal of the volume loss (low volume loss equates to high wear resistance), or using a particular grade (usually a WC-6Co grade with hardness of 92.0 HRA) as a reference, and reporting the performance of the grade as a percentage of this standard. Some caution must be exercised when comparing values reported by different manufacturers. Cemented carbide manufacturers have not agreed to a single test method, and there will be variation in the values and the units used to report wear resistance.

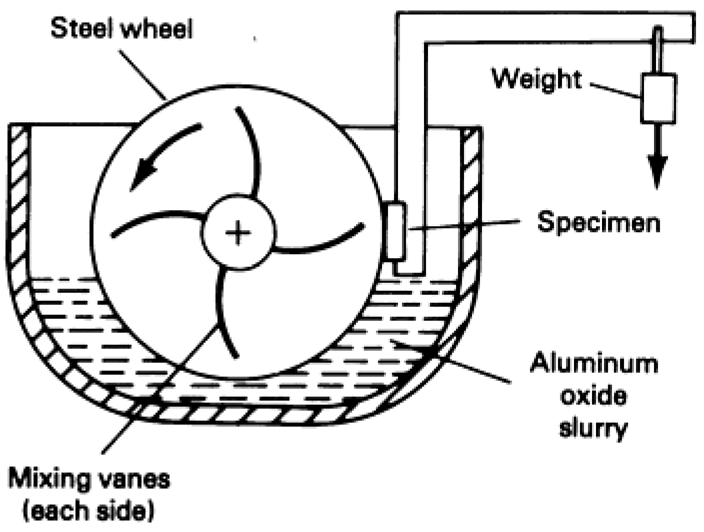

Fig. 5 Schematic of abrasive wear resistance apparatus

Another method involves a pin-on-disk apparatus (Ref 4). In this test, a resin-bonded diamond-covered disk is rotated at approximately 40 rev/min. A load is applied through a square WC-Co sample that is swept and rotated against the diamond wheel. The volume of the sample is determined before and after, and the volume loss is determined. Values are reported in a manner similar to that of the ASTM procedure above.

Figure 6 shows the relationship among fracture toughness, hardness, WC grain size, and abrasive wear resistance (Ref 4). The grades shown as 6C, 6M, 6F, 12C, 12M, and 12F represent 6 and 12% cobalt grades with coarse, medium, and fine grain size, respectively. The abrasive wear resistance increase with decreasing cobalt content and decreasing grain size. The abrasive wear resistance appears to be influenced more strongly by the WC grain size than by the cobalt content.

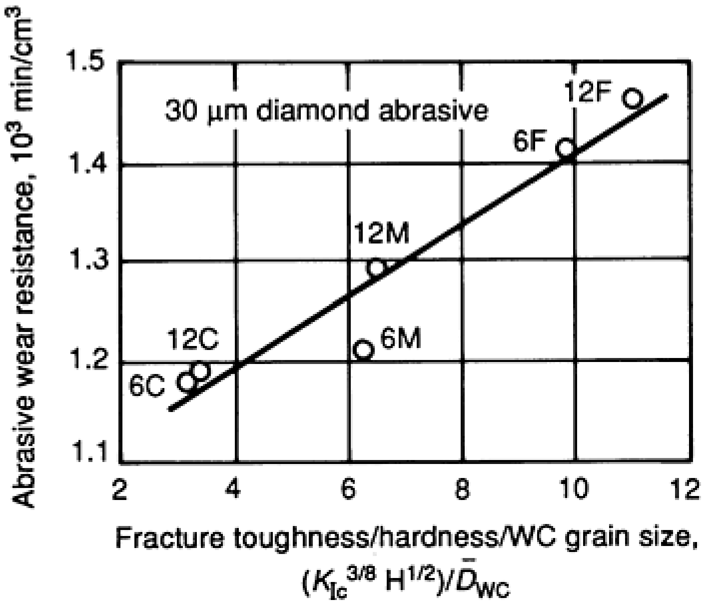

Fig. 6 Results of abrasive wear resistance tests. See text for description of data points. Source: Ref 4

The results of an abrasion test cannot be used to described the performance of a carbide grade when anything other than pure abrasive wear is present. For example, when cratering or dissolution wear is taking place during machining

operations, abrasion resistance test results are not meaningful. The same can be applied to metal pickup or galling during metal forming. In summary, abrasive wear resistance test results can only be applied to those instances when abrasion is the dominant wear mechanism.

Erosion resistance of carbides is important in applications such as sand blast-spray nozzles, seals in slurry pumps, and component parts in the oil industry. The success of carbides as an erosion-resistant material is again due to its unique composite structure of wear-resistant WC particles in a ductile cobalt matrix (Ref 4, 6).

The erosion resistance test involves impacting the WC-Co surface with 50 μm alumina particles at over 100 m/s (325 ft/s) for a set period of time under an inert gas carrier. The volume of the resultant crater is determined and reported as a volume loss. The smaller crater volumes equate to improved erosion resistance. Figure 7 illustrates a test apparatus for gas stream alumina particle erosion tests.

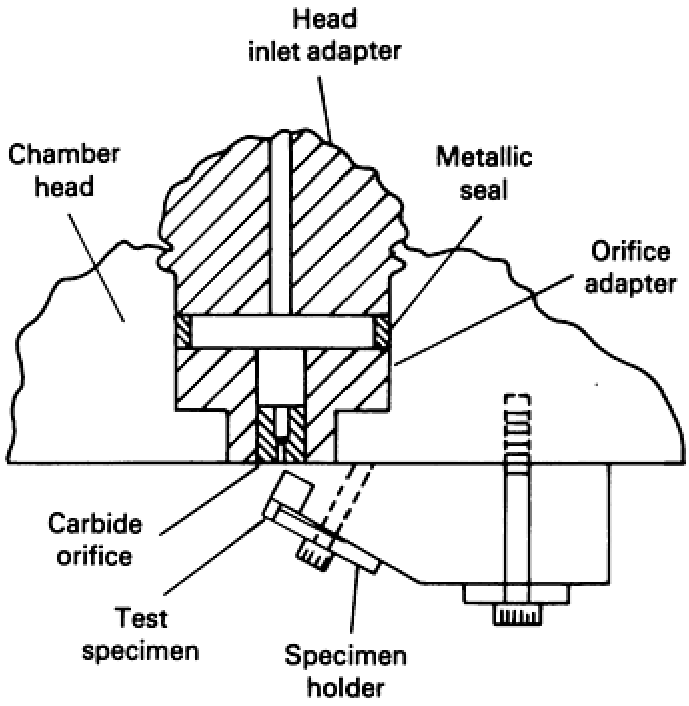

Fig. 7 Schematic of specimen fixturing for particle erosion testing. Source: Ref 6

The performance of carbides in erosion tests closely parallels their abrasive wear performance: the erosion resistance increases with decreasing cobalt content. The effect of WC grain size is not as strong as in straight abrasion, but the erosion rate does decrease slightly with increasing carbide grain size for cobalt percentages greater than 15%. Figure 8 shows the relationship between crater volume and the cobalt volume fraction. This relationship suggests that a binderless carbide (<5 vol%) would be preferred for erosion applications. However, grades with less than 5 vol% binder tend to exhibit higher wear rates due to the presence of increased grain boundary porosity after consolidation (Ref 6). These binderless alloys may not have the fracture toughness required to handle the thermal or mechanical loading that will be encountered in service. As such, design engineers may be required to compromise some erosion resistance for improved structural integrity and mechanical reliability.

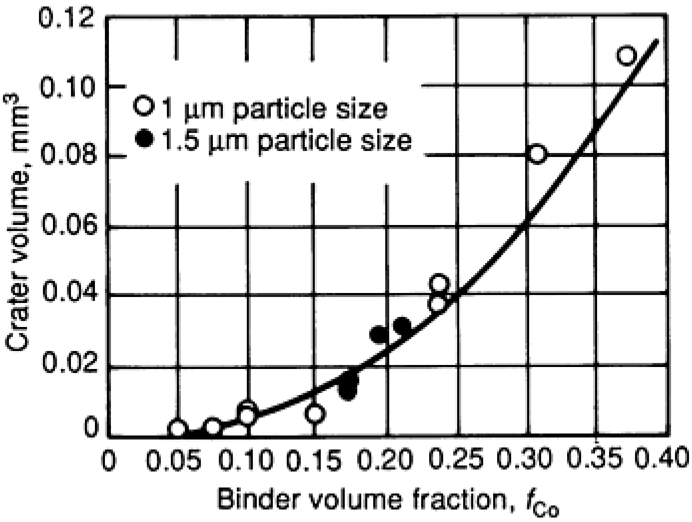

Fig. 8 Results of particle erosion tests. Source: Ref 6

Corrosion resistance is not typically thought of as a requirement for carbides, and in terms of straight corrosion resistance, there are commercially available materials that are clearly superior. However, when a combination of corrosion resistance, wear resistance, stiffness, toughness, and thermal conductivity is required--such as for rotary mechanical seals in industrial pumps--cemented carbides are the material of choice.

The corrosion resistance of carbides is limited by the susceptibility of the cobalt binder to chemical attack, although there are some corrosive media that attack WC. The corrosive media typically dissolve the cobalt binder from the matrix, leaving behind a weak, unsupported skeleton of tungsten carbide grains, which are easily abraded away. The corrosion resistance of straight WC-Co alloys is, in general, inversely related to that of the binder content. The straight substitution of nickel binder for cobalt does provide limited improvement in both corrosion and oxidation resistance. There are several grades available that utilize chromium additions to the cobalt binder to improve corrosion resistance. Chromium, however, promotes the formation of the carbon-deficient η phase with a resultant decrease in toughness and strength. The development of nickel binder grades alloyed with chromium, molybdenum, and other elements has resulted in a significant improvement in corrosion resistance with little sacrifice in strength or toughness. Figure 9 shows corrosion resistance versus pH for three different types of materials: WC-Co, alloyed WC-Ni, and TiC-Ni cermets (Ref 7). Although TiC-base cermets exhibit superior corrosion resistance, their use has been severely limited due to their inferior strength and lower thermal conductivity.

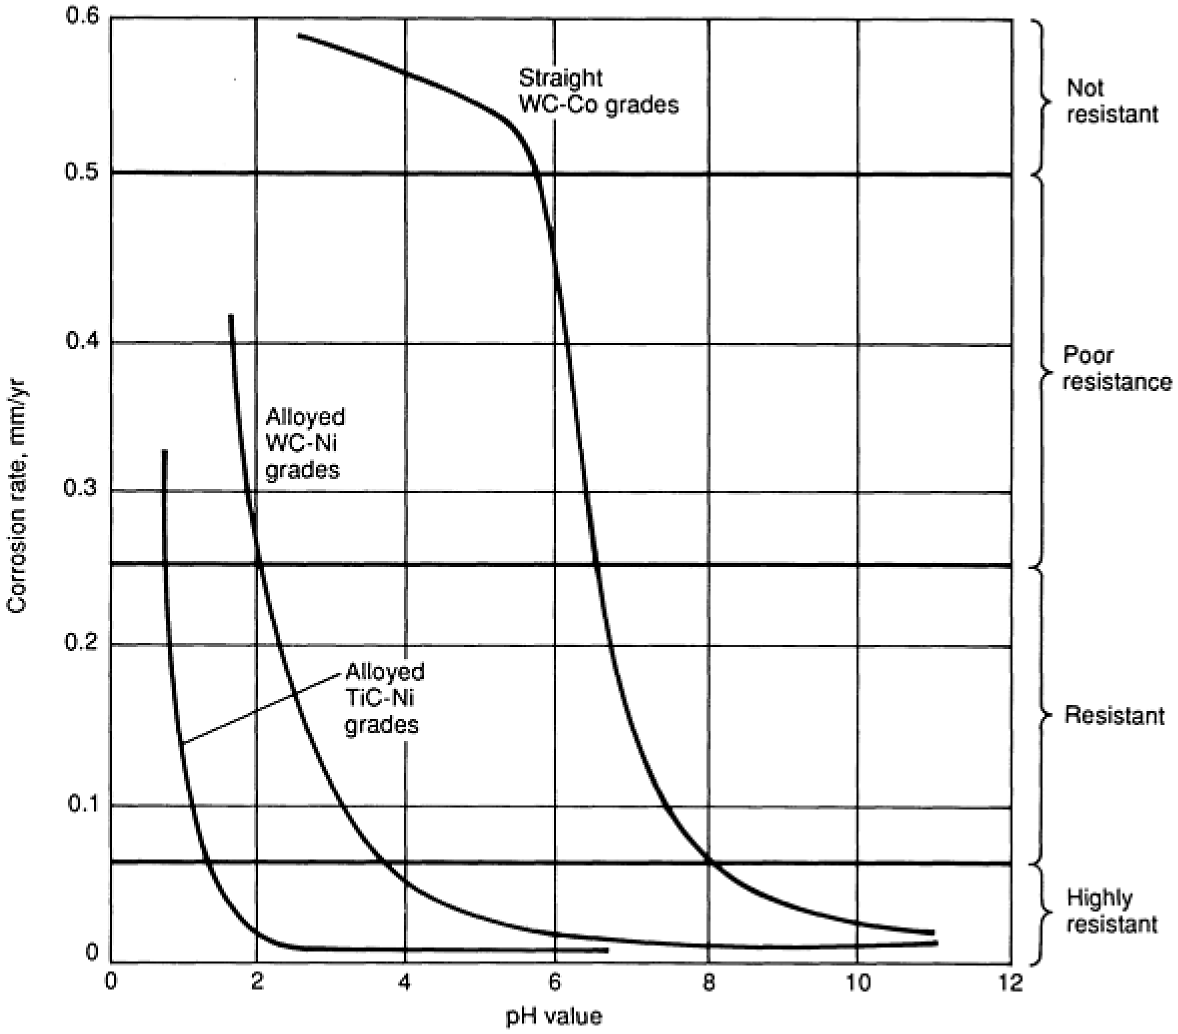

Fig. 9 Corrosion resistance of cemented carbides. Source: Ref 7

Corrosion resistance is determined using immersion methods. Test specimens are immersed in the media for a set period of time, at a constant temperature, and at a known pH level. The corrosion behavior of the material is determined by one of three methods. The first is a metallographic examination in which a cross section of the material is polished, etched, and observed at high magnifications to determine the depth of binder removal. The second involves tumbling the test specimen after immersion. Tumbling abrades the unsupported network of WC grains and leads to a final weight loss measurement. The third method utilizes atomic absorption techniques to measure the amount of binder (cobalt or nickel) that has been dissolved in the corrosive media. A low concentration of binder in the media indicates a high corrosion resistance. Additional information on the corrosive behavior of carbides can be found in the article "Corrosion of Cemented Carbides" in *Corrosion,* Volume 13 of *ASM Handbook* (1987).

Friction and Wear of Metal-Matrix Composites

P.K. Rohatgi, Y. Liu*, and S. Ray, University of Wisconsin-Milwaukee**

Introduction

FOR MOST OF THE PAST CENTURY, research and development in tribology have been directed at meeting the severe conditions of mechanical systems, such as advanced engines, that require increasingly high working temperatures and running speeds. The development of new materials that can meet these severe requirements has become a major imperative. Metal-matrix composites are attracting considerable interest worldwide because of their superior mechanical and tribological properties. These advanced materials have a metal matrix in which nonmetallic fibers, particles, or whiskers are dispersed. For use in tribological applications, metal-matrix composites must be able to support a load without undue distortion, deformation, or fracture during performance and to maintain controlled friction and wear over long periods without seizure under working conditions (Ref 1).

This article will review the structure, processing, and properties of those metal-matrix composites (both particulate and fiber reinforced) that have been studied for their tribological properties. In addition, it will discuss the current and potential uses of metal-matrix composites in applications where tribological properties are of paramount importance, such as electrical contact brushes, bearings, pistons, cylinder liners, and brake drums.

A variety of nonmetallic particles have been dispersed in different metal systems to develop metal-matrix nonmetallic particle composites; a selected list of these particles is given in Table 1 (Ref 2, 3, 4). These particles can be roughly divided into two different groups on the basis of hardness: (1) hard particles with hardness of 4 to 30 GPa (580 to 4350 ksi), such as SiC, Al_2O_3, and silica, and (2) soft particles with hardness below 2 GPa (290 ksi), such as graphite and MoS_2, which are primarily added for solid lubrication purposes. Particles with values between these ranges are considered to have intermediate hardness. This arbitrary division is based on the fact that composites containing hard particles generally exhibit different friction and wear behavior (because of different wear mechanisms) than composites containing soft particles in alloys with the same matrix.

Table 1 Density and hardness of selected particles for metal-matrix particle composites

Particle type	Density		Mohs hardness	Hardness	
	g/cm^3	**lb/in.^{3}**		**GPa**	**ksi**
TiC	4.93	0.178	9	20-30	2900-4350

(a) Polytetrafluoroethylene

Particulate-reinforced composites cost less than fiber-reinforced composites, owing to the lower costs of the particles. In addition, the mechanical and physical properties of particle composites are generally isotropic. Cast metal-matrix particulate composites represent the lowest cost composites, and these have found the most tribological applications.

Table 2 lists a number of metal-matrix composites synthesized using the two types of particles, along with particle size, volume fraction, matrix alloys, and methods of fabrication. The matrix alloys used for the synthesis of composites include those based on aluminum, copper, silver, iron, magnesium, steel, titanium, and cobalt. Synthesis techniques include powder metallurgy, mechanical alloying, spray dispersion, squeeze casting, stir casting, compocasting, and low-pressure infiltration. In recent years, the use of inexpensive liquid metallurgy techniques, including stir casting, squeeze casting, and pressure infiltration, has become widespread in the production of metal-matrix particulate composites (Ref 5, 6, 7).

Table 2 Selected metal-matrix nonmetallic particle composites and methods used for their synthesis

Particle type	Dispersoid size, μm	Vol%	Matrix alloy	Method of fabrication
SiC	1-20	0.3-20	Al-Si, Al-Cu, Al-Cu-Mg	Vacuum slurry casting, squeeze casting, powder metallurgy
TiC	<40-212	8-40	Al-Cu, Al-Mg, Ti-Al-V, steel	Slurry casting, squeeze casting, powder metallurgy, laser melt-particle injection, casting
Al_2O_3 (bauxite), 87.9% Al_2O_3	0.01-200 <50	0.5-10 1-20	Al-Mg, Al-Cu, Al-Si, Cu, steel, Mg	Slurry casting, squeeze casting, powder metallurgy
WC	106-150	. . .	Ti-Al-V, Co-base	Laser melt-particle injection, powder sintering
M_7C_3 (Cr-rich)	18-38	. . .	Co-Cr	Powder metallurgy
ZrO_2/$ZrSiO_4$	5-80	1-4	Cu, Al, steel	Slurry casting, bottom pouring, spray dispersion, powder metallurgy
TiO_2/MgO	. . .	10	Cu, Al, steel	Slurry casting, bottom pouring, spray dispersion, powder metallurgy
Glass/SiO_2	30-110	2-10	Al-Mg, Cu	Slurry casting, bottom pouring, powder metallurgy
Mica/talc	40-180	3-10	Al-Cu-Mg, Ag, Cu-Sn	Slurry casting, compocasting, powder metallurgy
Shell char	125	15	Al-Si-Mg	Slurry casting, squeeze casting
Graphite	15-800	1-750	Al, Cu, Ag, iron	Slurry casting, squeeze casting, powder metallurgy
PTFE	. . .	20-40	Cu, Ag, Cu-steel	Powder metallurgy
MoS_2	0.5/5	1-80	Cu, Cu-Ta	Powder metallurgy

Mechanical Properties of Metal-Matrix Composites

The mechanical properties of a material are important in determining its tribological behavior. Wear can often be attributed to cracks that originate in the heavily deformed subsurface region and propagate to the surface, thereby releasing debris. Therefore, the deformation and fracture behavior of a material under both uniaxial and triaxial load assumes importance in the context of its tribological response.

In metal-matrix composites, mechanical properties depend on the amount, size, shape, and distribution of the dispersed phase apart from the mechanical properties of the matrix material and on the nature of the interface. By definition, a composite material generally requires an amount of dispersed phase (> 1 vol%) of a size (> 1 μm) that allows this constituent to be load bearing and not act merely to control the movement of dislocations, as in dispersion-strengthened materials. The shape of the dispersed phase is so important in determining its load-bearing capacity that composites have been classified on this basis: (1) fiber-reinforced composites with both continuous and discontinuous fibers and (2) particle- or whisker-reinforced composites. The aspect ratio (that is, the ratio of length to diameter of a fiber) generally characterizes the shape. In continuous-fiber composites, the load is applied directly to both the matrix and the fiber. In discontinuous-fiber composites or particle-reinforced composites, the load is transmitted to the dispersoid through the matrix. Mismatch of strain in the matrix and the dispersoid across the interface results in a shear stress at the interface. The transfer of load to the dispersed phase depends on the magnitude of the shear stress as described in simplistic "shear lag" models for discontinuous fibers and particles in a matrix (Ref 8, 9). If the shear stress that develops at the interface exceeds the strength of the interface, debonding will occur at the interface, and this may develop into a crack that can propagate. For a given condition of loading, the load shared by the dispersed phase increases with its aspect ratio.

Going beyond the framework of elasticity theory, the presence of hard dispersed particles will cause additional strain hardening; this may not be significant in the case of soft particles with a shear modulus lower than that of the matrix alloy. Thus, composites with soft particles such as graphite have lower strength compared with the matrix alloy, as shown in Fig. 1 (Ref 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25). The strength of composites that contain hard particles increases with the volume percentage of particles in the composite. However, the ductility of composites that contain both soft and hard particles decreases compared with that of the matrix alloy (Fig. 2) presumably because of debonding of the interface at low strain, as often indicated by serrations in tensile stress-strain diagrams (Ref 26).

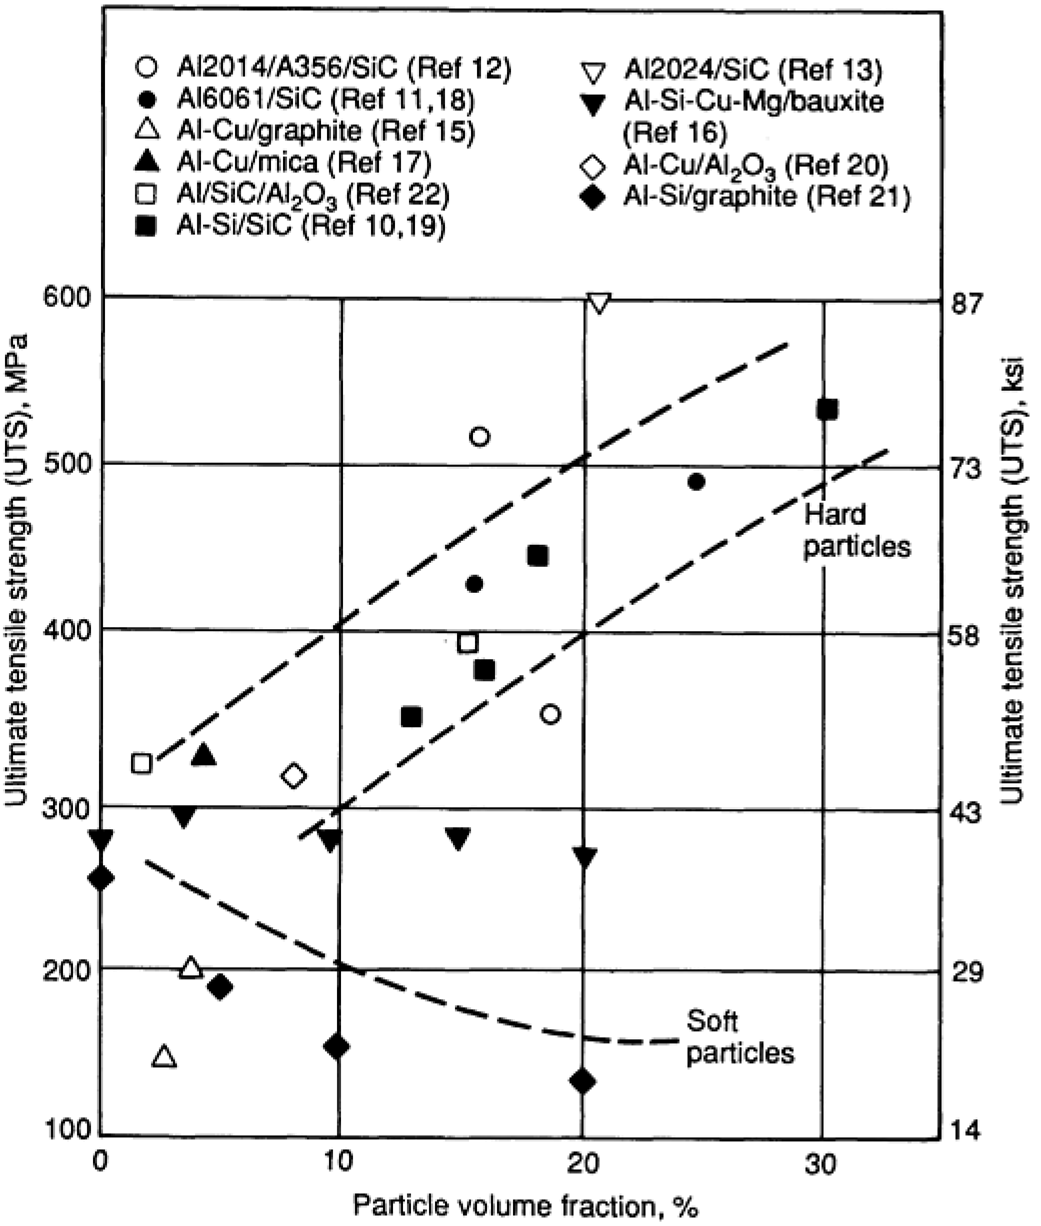

Fig. 1 Ultimate tensile strength as a function of particle volume fraction for aluminum alloy composites

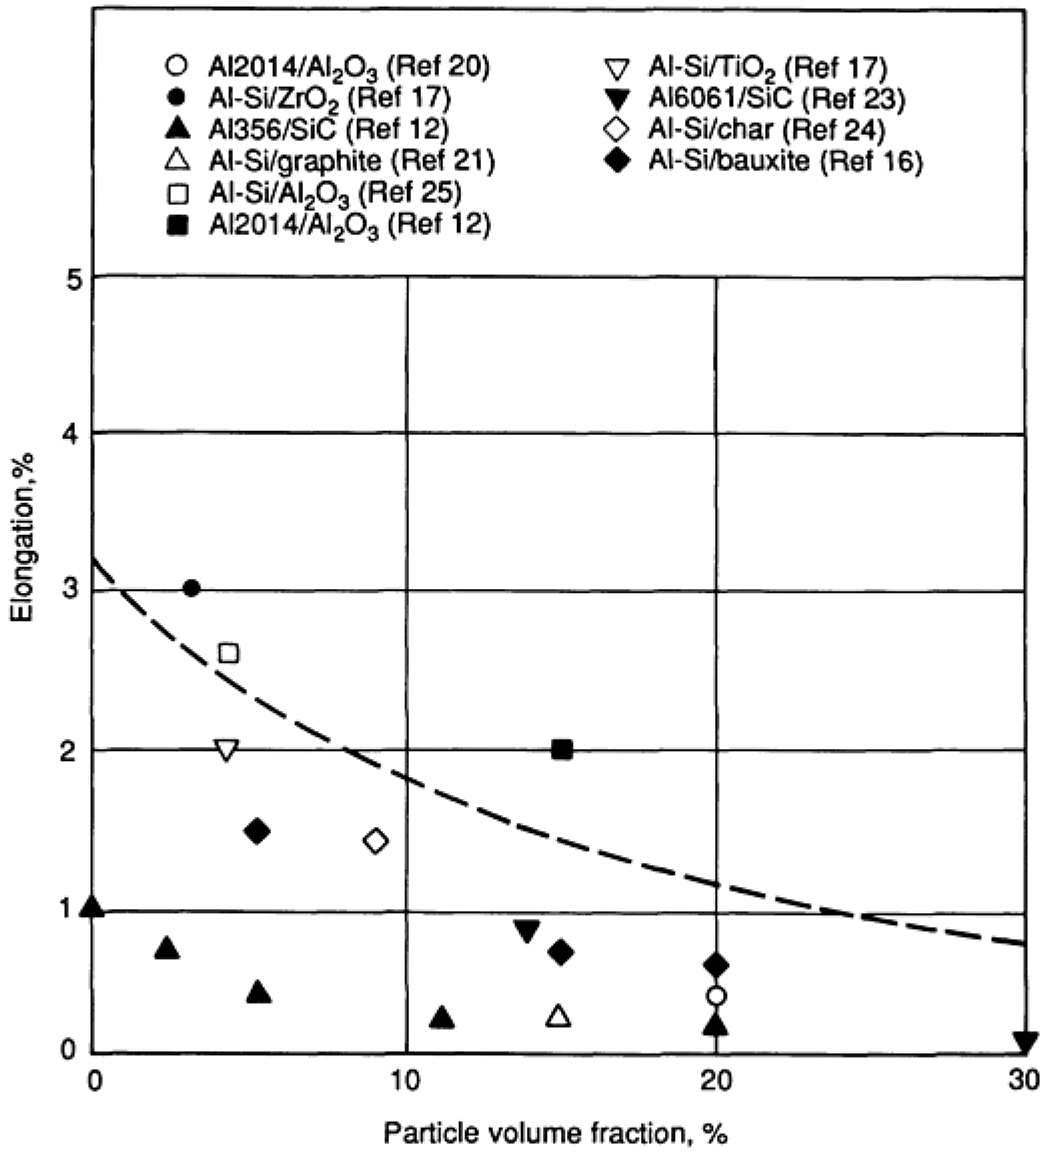

Fig. 2 Elongation as a function of particle volume fraction for aluminum alloy composites

The mechanical properties of discontinuous-fiber composites are similar to those of particle- or whisker-reinforced composites, except that the strength of discontinuous-fiber composites increases with aspect ratio. In the case of continuous-fiber composites, strength increases with volume fraction of the fibers (Fig. 3), even for soft fibers such as graphite (Ref 27), because these fibers are strong. The physical properties of the fibers used to reinforce metal-matrix composites are given in Table 3. The mechanical properties of fiber-reinforced metal-matrix composites are given in Table 4.

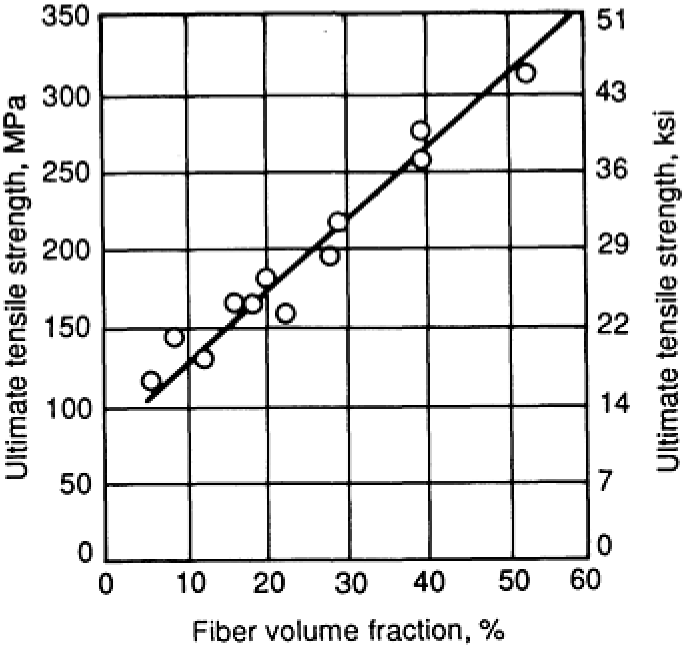

Fig. 3 Ultimate tensile strength of squeeze-cast continuous graphite-fiber-reinforced aluminum alloy composites as a function of fiber volume fraction

The fracture toughness of particulate composites is low, and it decreases with volume fraction of a dispersed phase such as SiC, as shown in Fig. 4 (Ref 10, 23, 28, 29). A weak interface leads to cracks at low strain, and a low fracture

toughness value indicates their easy propagation. In the context of wear, these two properties are critical to the generation and propagation of cracks, resulting in wear debris. Pores in composites may act as preexisting crack nuclei in the system, waiting to become unstable at appropriate stress levels (Ref 30). Porosity thus increases composite wear rate.

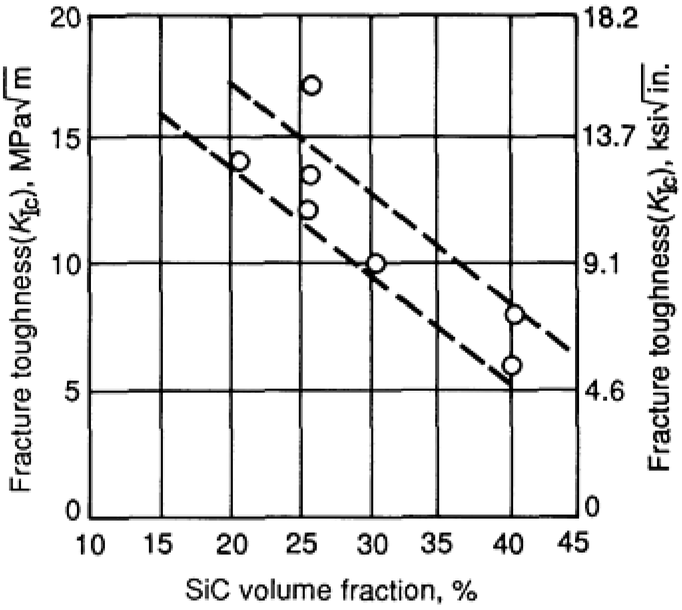

Fig. 4 Fracture toughness of aluminum alloy composites containing SiC as a function of volume fraction of SiC

During tribological interaction between two surfaces, temperature rises significantly at and near the surface, and the mechanical properties of the composites at elevated temperatures may be of direct relevance. The dispersed hard particles are helpful in retaining the high-temperature strength of the matrix (Ref 31). Also, the loss of strength due to dynamic recrystallization is counteracted by the presence of particles. Metal-matrix composites can thus have superior mechanical properties at elevated temperatures, even though the room-temperature properties may not look encouraging in certain systems.

Tribological Behavior of Metal-Matrix Particulate Composites

Friction and Sliding Wear. Friction and wear behavior of metal-matrix composites depends on the nature of particle reinforcements in close relation to the matrix containing them. The particles can be softer or harder compared with the matrix. Ceramic particles generally used as reinforcements include carbon, silicon carbide, and alumina, which have low adhesion to a metallic counterface. The asperity of the counterface can easily plow through softer particles such as char (carbon); it cannot do so through harder particles such as alumina or silicon carbide.

Figure 5 shows the variation of specific wear rate as a function of volume fraction of particles in different systems (Ref 12, 32). Char is a soft particle that contains carbon and other hard mineral oxides, and composites containing char exhibit much wear. Alumina is harder than char but softer than silicon carbide, and an aluminum-alumina composite shows higher wear than an Al-SiC composite but lower wear than an aluminum-char composite. However, aluminum-base composites that contain graphite have the lowest wear, because graphite is not only soft but also shears easily along the basal plane of its hexagonal close-packed lattice in suitable environments and acts as a solid lubricant. Composites containing a solid lubricant such as graphite have low wear because of its transfer onto the tribosurfaces and the subsequent formation of a lubricating film between the matrix of the composite and the counterface. Thus, it may be concluded that the harder the reinforcing particles, the lower the sliding wear in a composite, with the exception of solid lubricating dispersoids of the right crystal structure, which impart low wear rate despite their low hardness. Another interesting observation in Fig. 5 is that wear resistance can be improved by increasing the volume fraction of either hard or soft particles in the range of conditions investigated.

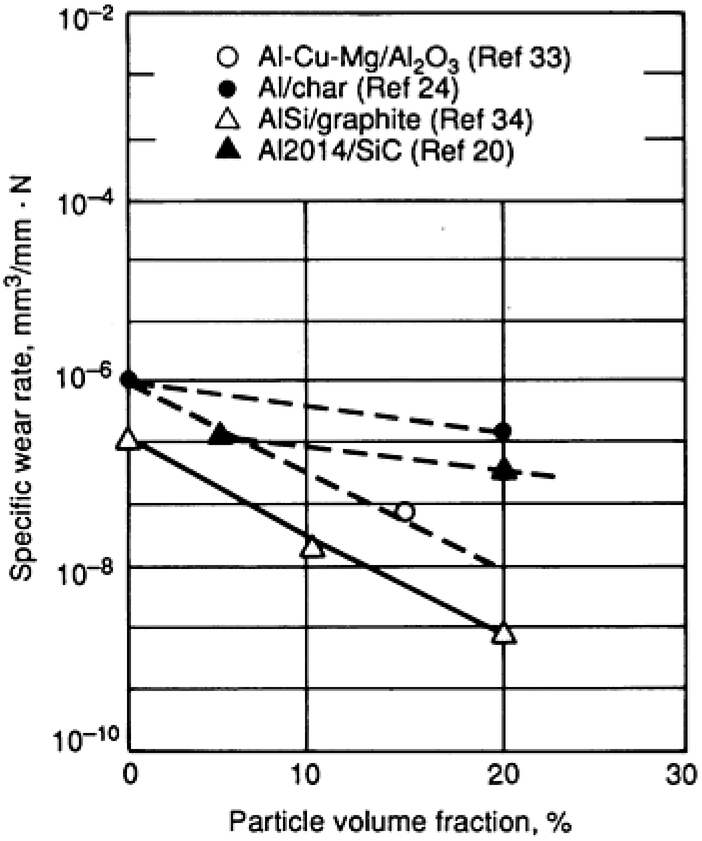

Fig. 5 Specific wear rates for several aluminum alloy particulate composites sliding against steel as a function of particle volume fraction

The friction coefficient values for various composites are given in Fig. 6. It seems that particles with higher hardness result in higher coefficients of friction. Figure 6 can be divided roughly into three overlapping regions (Ref 24, 33, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44):

- *Region 1:* μ= 0.3 to 0.5, the range of values for composites containing hard particles
- *Region 2:* μ= 0.25 to 0.4, the range of values for composites containing particles of intermediate hardness
- *Region 3:* μ= 0.10 to 0.30, the range of values for composites containing soft particles

However, this classification does not reflect matrix characteristics and thus can be applied only to composites of the same or similar matrix. The hard particles in composites result in larger plastic deformation due to asperity-asperity interaction during sliding and contribute to higher coefficients of friction despite reduced contribution of adhesion between the particle and the matrix. In region 3, a lubricating film forms on the mating surface, caused by the smearing of soft solid lubricating particles during the sliding process. In region 2, although a transfer layer may form during sliding, this layer cannot reduce the coefficient of friction significantly because it is not a lubricating film. Solid lubricating films are responsible for lower friction coefficients in composites that contain solid lubricants such as graphite or MoS_2. Rohatgi *et al.* (Ref 45) have published detailed results on the tribological behavior of metal-matrix/graphite-particle composites. Their results indicate that when the volume fraction of graphite in the composite is greater than 20 vol%, the coefficient of friction is close to 0.2 regardless of the matrix. Apparently, above 20 vol% graphite, the graphite film covers the entire surface and prevents direct metal-to-metal contact, as shown in Fig. 7 (Ref 40, 42, 43, 45, 46, 47, 48, 49, 50). Under these conditions, the friction coefficient is not a significant function of the matrix alloy chemistry.

Fig. 7 Coefficient of sliding friction as a function of volume fraction of graphite particles in metal-matrix composites sliding against steel (except those with a silver matrix)

Friction and Abrasive Wear. The abrasion resistance of a material generally is determined by two different types of tests: (1) low-stress tests, such as rubber wheel abrasion tests (RWAT; for details, see ASTM Standards G-65 and B-611) and (2) high-stress tests, such as pin-on-disk and pin-on-drum types of tests. In low-stress tests, the abrading particles do not break; in tests employing high stress levels, the abrading particles break. The abrasive particles are generally rounded sand (SiO_2), crushed quartz, or silicon carbide particles of different grit sizes and shapes. The size and shape of abrading particles, as well as their relative hardness with respect to the composite being tested, are important parameters in determining the extent of wear. Bhattacharrya and Bock (Ref 51) examined the effects of different abrasive particles on the abrasive wear of engineering materials and concluded that alumina is more aggressive than silica sand. In monolithic materials, it has been observed (Ref 52) that wear volume increases rapidly with grit size of abrading particles up to a critical diameter; beyond this size, wear increases at a slower rate. When the size of the abrading particle is less than 1 μm, the wear is no longer by abrasion. In metal-matrix composites, as in monolithic materials, abrasive wear involves gouging, grooving, and plastic deformation caused by penetration of hard abrading particles (Ref 53). The abrading particles may also interact with the dispersed hard particles in the composite. In RWATs, the stress developed during this interaction between hard particles cannot exceed a limiting stress required for local elastic deformation of the rubber wheel to engulf the abrading particle. In high-stress tests employing the rigid backing surface of a disk or drum, the particle interaction can be very severe, leading to widespread fracture of the hard but brittle particles.

Specific abrasive wear rates as a function of volume fraction for several hard particles dispersed in aluminum matrices are shown in Fig. 8 (Ref 14, 16, 37, 54). The wear rates decrease with an increase in volume fraction of particles in a manner

similar to those observed in adhesive wear. For a given volume fraction of particles, composites that contain harder particles exhibit a lower wear rate. Although the values of abrasive wear show considerable scatter, the specific wear rate for aluminum-base composites containing hard particles is 10^{-6} to 10^{-7} $mm^3/mm \cdot N$ when the volume fraction of particles is less than 40%. Tawarada *et al.* (Ref 55) have pointed out that the specific wear rate for Al-4.5Mg alloy containing more than 50% Al_2O_3 particles is extremely low, of the order of 10^{-9} to 10^{-10} $mm^3/mm \cdot N$.

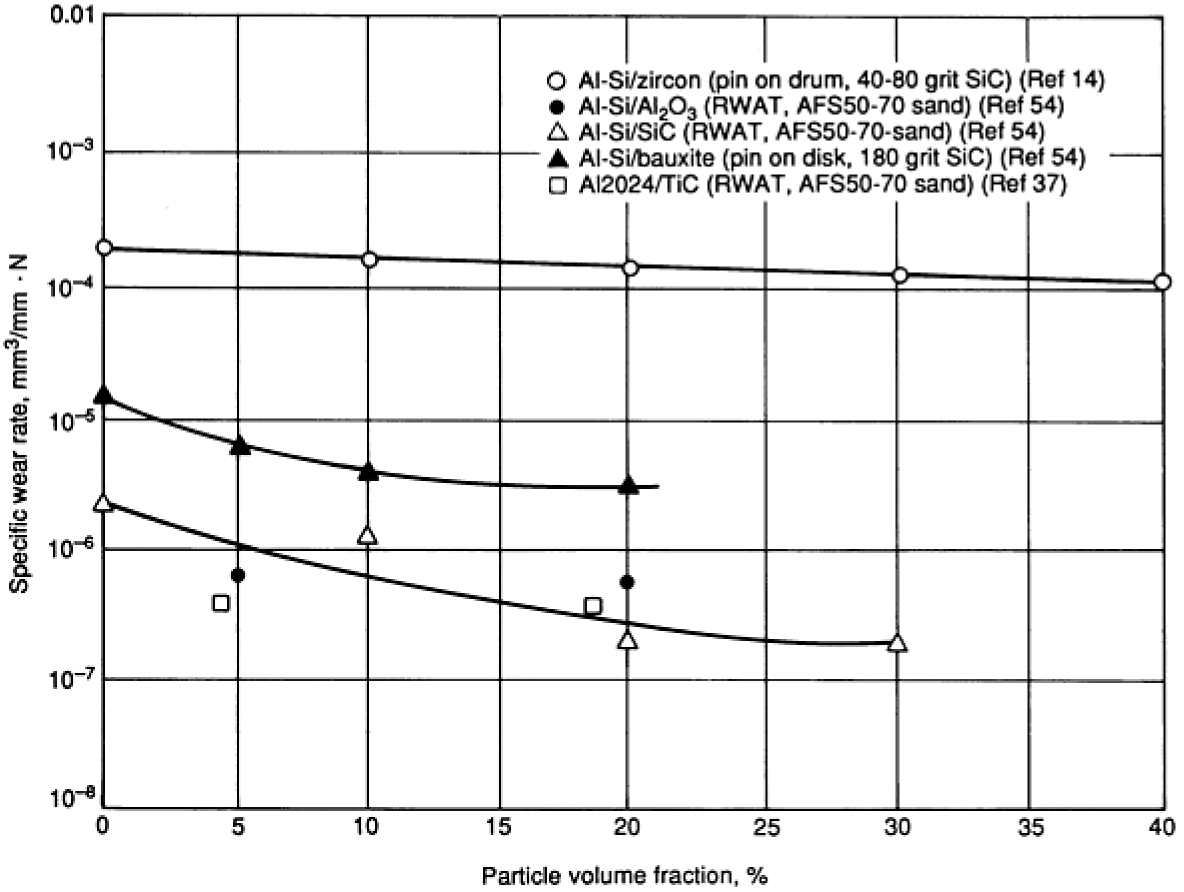

Fig. 8 Specific abrasive wear rate as a function of particle volume fraction in aluminum alloy composites

The improvement in abrasion wear rate of various metal-matrix composites over that of the base alloy is a function of the volume of different reinforcing particles when subjected to RWATs (Fig. 9) (Ref 56). The properties of the dispersoid did not significantly affect these results, probably because of low-stress interaction between the dispersoid and the abrading particles at a level much lower than the hardness of the dispersoids. Under high-stress conditions, the wear rate decreases almost linearly with the volume fraction of dispersoids in a composite. Similar results have been reported for copper-base hard-particle composites (Ref 57). Apparently, the particle spacing decreases with an increase in volume fraction, and any cracks formed easily propagate through the reduced distance in the ductile matrix region to reach the neighboring particles; this results in faster wear of the composites (Ref 58, 59, 60).

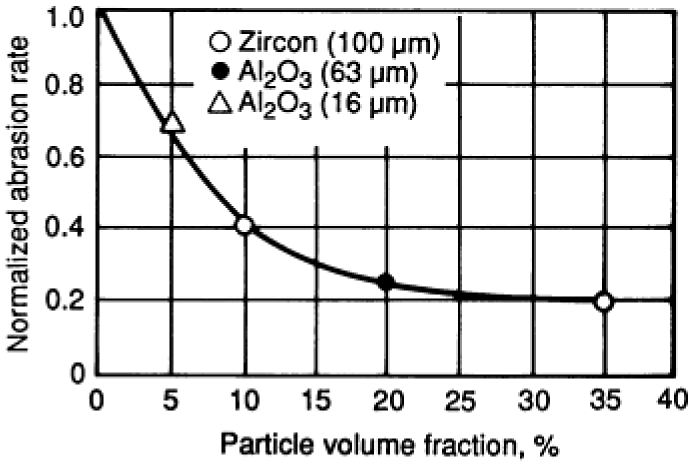

Fig. 9 Normalized abrasion rate as a function of particle volume fraction for aluminum alloy composites under low-stress abrasive wear

Very few publications on steel-base particulate composites are available in open literature. Recently, Halley *et al.* (Ref 61) have reported that the abrasive wear volume of tool steel (0.6-0.9C-10Cr-Mo) with 17 vol% TiC particle composites was lower by 54% compared with similar tool steels. Other investigators (Ref 62) also report that wear rate decreases with an increase of TiC volume fraction for steel-base TiC particle composites.

Under abrasive wear, the coefficient of friction in composites containing hard particles is also a function of the volume fraction of dispersoids. As the volume fraction of hard particles increases, the coefficient of friction decreases for both aluminum-base (Ref 42) and copper-base (Ref 57) composites. The increase in the volume fraction of hard particles in the matrix alloy reduces the area fraction of matrix, and thus there is enhanced ceramic-ceramic contact. The friction coefficient for ceramic-ceramic contact can be 0.25 or less (Ref 57, 63), and that for metal-metal contact is generally much higher (Ref 57, 64). The increase in the relative contact area involving ceramic particles increases the contribution of ceramic-ceramic contacts, resulting in an overall decrease in friction coefficient.

Friction and Erosive Wear. In most cases, the abrasive wear resistance of composites increases with increasing particle volume fraction of hard particles, as discussed above. However, in the case of erosive wear (for details, see ASTM Standard G-76), opposite results have been reported (Ref 65, 66, 67, 68), as shown in Fig. 10. The steady-state erosion rate for 75 to 200 μmquartz erodent at 60 ms^{-1} and an impact angle of 60° increases with an increase of carbide content in both iron- and cobalt-base composites. Similar results have been obtained for other impact angles. In addition, if the matrices are changed from metals to ceramics, the erosion rate decreases with the content of carbides in ceramics (Fig. 10). Ball and Patterson (Ref 67) have pointed out that the minimum in erosive wear rate appeared at 34 vol% binder in WC-Co cermets. A similar result has been reported in the same system for slurry erosive wear (Ref 68). It has been established that, in erosive wear, the angle of impact is very important. In ductile materials, erosive wear is maximum at an impact angle of 15° to 30° for brittle materials, however, this angle is about 90°. Goretta *et al.* (Ref 69) have found that erosive wear rates reach a maximum when the impact angle of the erodent Al_2O_3 was 15° to 30° in Al-20SiC particle composites, and the wear rates of the Al-SiC composites are higher than that of the base alloy under impact angles from 15° to 90°. It is believed (Ref 65, 66, 67, 68, 69, 70) that erosion rates are affected by particle size, particle agglomeration, heat treatment, erodent hardness, impact angle and velocity, and volume fraction of hard particles (or second phase). It has been claimed that erosion rates of metallic alloys are not likely to be reduced by additions of hard particles, except for cases when relatively soft particles (such as quartz abrasive) are used as erodents (Ref 66).

Fig. 10 Erosion rate as a function of particle volume fraction for iron- and cobalt-base composites and cermets

Mechanisms of erosion include fracture-toughness-dominated wear and hardness-dominated wear. The former is applicable for ceramic composites with a lower amount of metal binder, but the latter is the criterion suitable for erosion wear in metal-matrix composites.

Effect of Particle Size. Figure 11 shows the effect of particle size on specific wear rates of composites under sliding wear conditions. The larger the particles, the lower the wear rate for composites that contain either hard or soft particles.

Similar results have been reported by Suwa *et al.* (Ref 21) for aluminum-graphite systems. It should be pointed out that for small sizes of hard particles ($\leqslant$20 μm), a change in particle size may not significantly affect wear results.

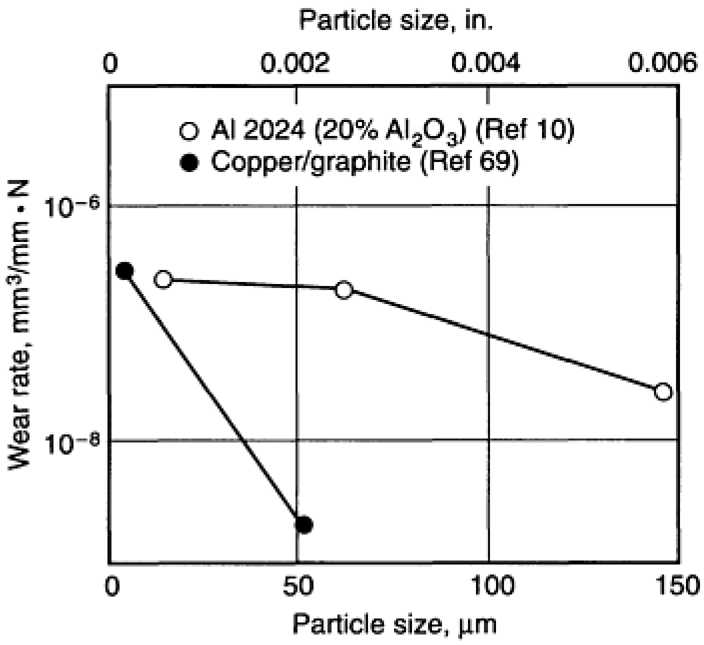

Fig. 11 Specific wear rate as a function of particle size for metal-matrix composites under sliding wear

The coefficient of friction for composites containing soft particles is affected by particle size. Tsuya (Ref 41) has reported that the value of the friction coefficient in sliding decreased from 0.4 to 0.2 in Cu-20WS_2 composites when the size of WS_2 increased from 0.1 to 0.2 μm. The effect of particle size on sliding friction coefficient is not clear for composites containing hard particles (Ref 20).

Desai *et al.* (Ref 71) have indicated that, under abrasive wear, dispersions of coarser carbide particles (chromium-enriched M_7C_3 carbide) reduced the wear of cobalt-base composites, as shown in Fig. 12. Similar results have been reported by Bhansali and Mehrabian (Ref 54) and by Tawarada *et al.* (Ref 55) for aluminum-base composites.

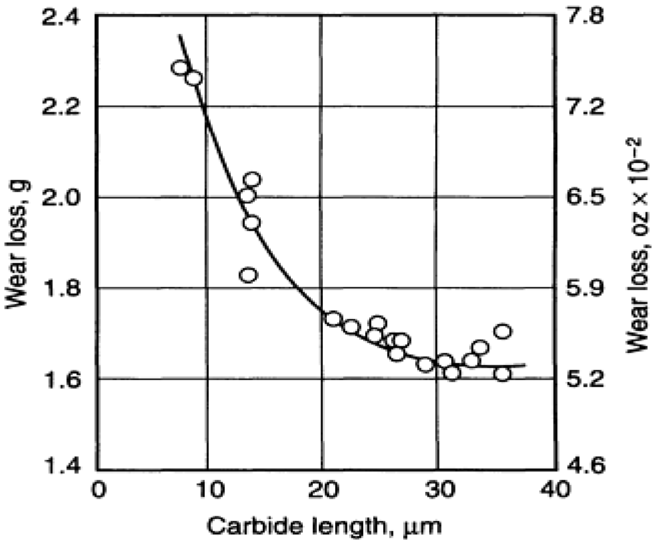

Fig. 12 Wear loss as a function of particle size (M_7C_3) for cobalt-base composites under the rubber wheel

The effect of hard-particle size on friction and abrasive wear in aluminum-base composites has also been studied (Ref 36). In aluminum-magnesium alloy base composites that contain SiC, the friction coefficient decreased as the average particle size decreased for a constant percentage of SiC particles.

Effect of Testing Parameters. The effect of normal load on wear of composites containing hard particles and particles of intermediate hardness has been reported for both adhesive (Ref 20, 24, 25, 38) and abrasive wear (Ref 14, 54, 55). Both wear rates increase as the normal load increases (Fig. 13). Similar results have been reported by Nath *et al.* (Ref 38), Murali *et al.* (Ref 24), and Yang and Chung (Ref 16). However, for certain composites that contain a high volume fraction of soft particles such as MoS_2 and WS_2, the wear rate decreases up to a limiting value of contact pressure and then increases, as shown in Fig. 14. This result is quite similar to that obtained during metal-to-metal sliding using solid lubricants (Ref 70), indicating that a lubricating film may form at the mating surfaces during sliding wear of composites that contain soft sulfide particles.

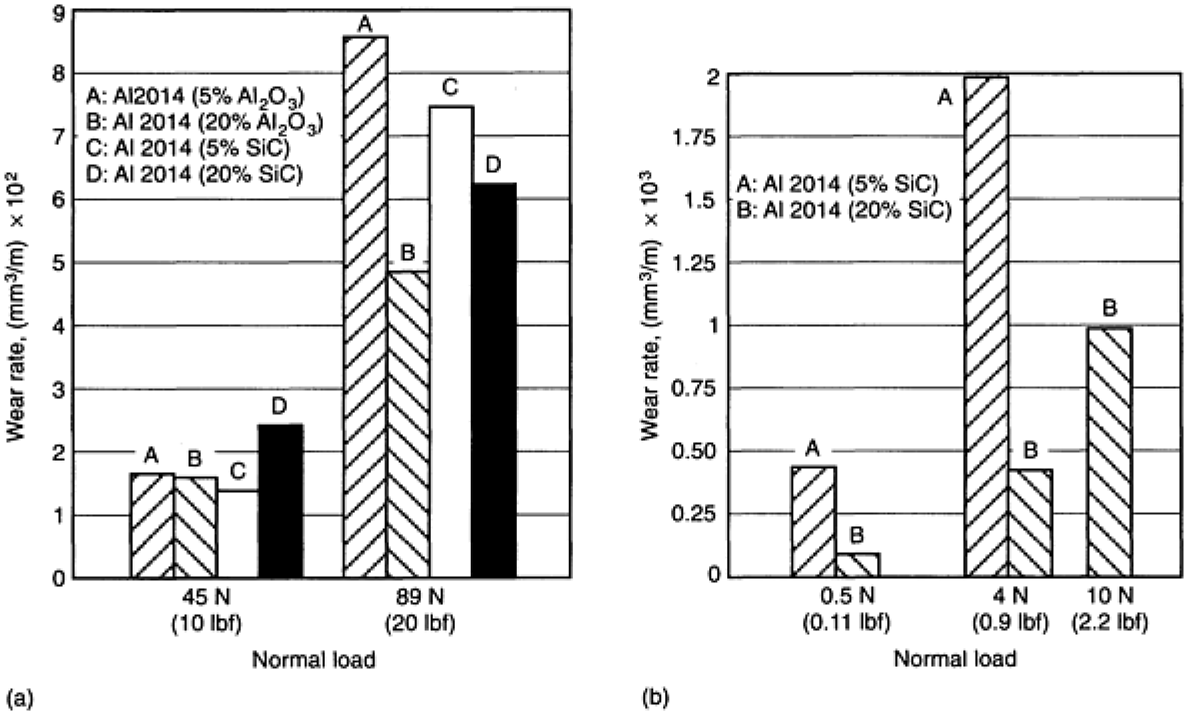

Fig. 13 Wear rate as a function of normal load in metal-matrix composites. (a) Under adhesive wear against steel. (b) Under abrasive wear in dry sand RWAT

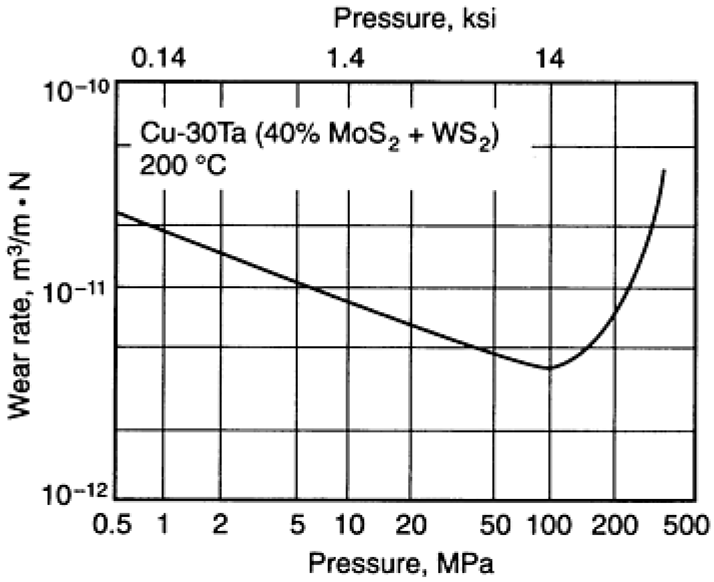

Fig. 14 Specific wear rate as a function of normal contact pressure for Cu-30T a base soft-particle composites under sliding wear

In composites that contain a lower volume fraction of soft particles, the tribosurface may not be completely covered by a film, and the wear volume increases with normal pressure, as shown in Fig. 15 (Ref 45). Similar results have been obtained for aluminum-lead composites by Mohan *et al.* (Ref 72).

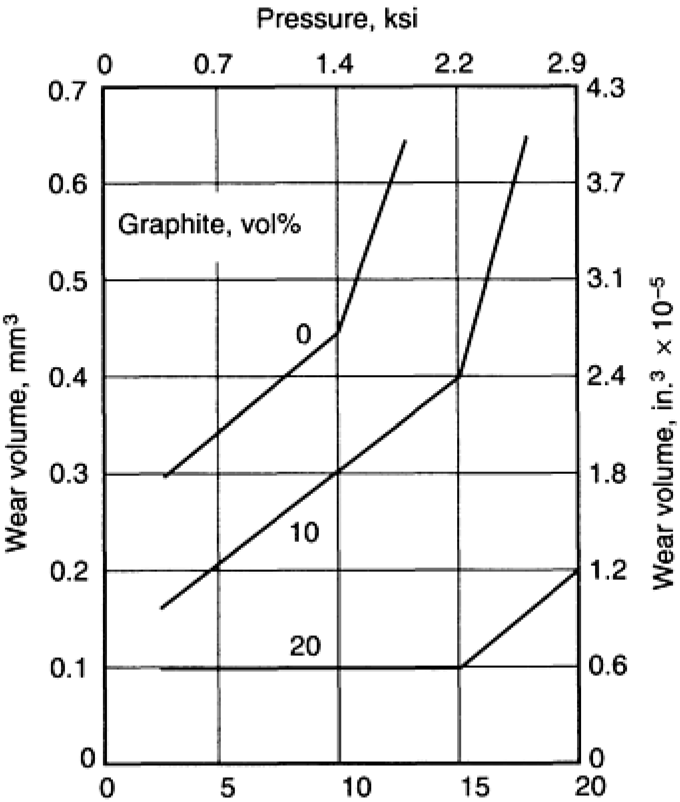

Fig. 15 Variation of wear with normal pressure in copper-base composites containing different amounts of

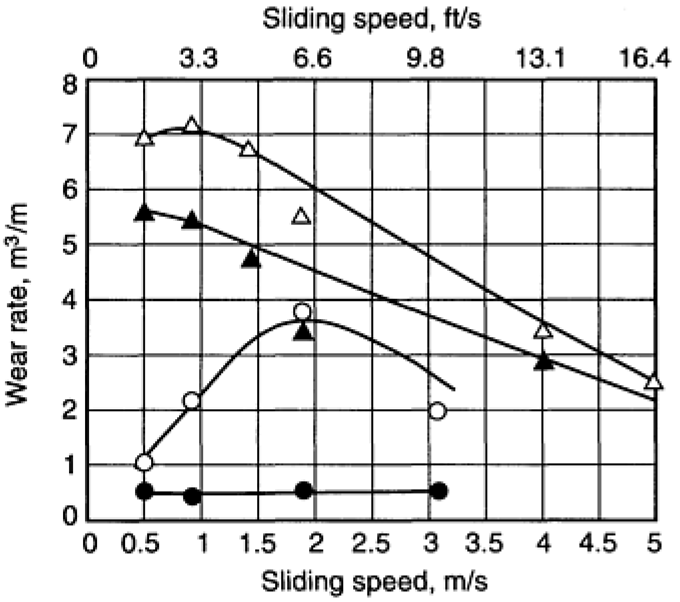
graphite particles.

The effect of normal load on friction under sliding wear for composites containing hard particles has been reported (Ref 16). The coefficient of friction tends to decrease as the normal load increases.

Keshavaram and co-workers (Ref 35) have reported that in aluminum alloy composites containing 10% glass, the wear rate decreases with an increase in sliding velocity (0.1 to 3 m/s) under adhesive wear. On the other hand, Suzuki *et al.* (Ref 73) have reported that, under abrasive wear, the wear (in microns) of an Al-12Si-50Al_2O_3 composite was almost constant as the sliding velocity increased from 3 to 8 m/s. When these results are converted into wear rate, the same trend observed by Keshavaram *et al.* (Ref 35) is evident.

The effect of sliding velocity on wear rate is more complex for composites that contain soft particles. Rohatgi *et al.* (Ref 45) have reported results for aluminum-graphite systems. The wear rate for an aluminum alloy composite containing 5% graphite decreases with increasing sliding speed (0.5 to 5 m/s) (Ref 74). Sliding speed does not affect wear rate significantly if the volume fraction of graphite particles increases to 15% (Ref 46), as shown in Fig. 16, indicating that the sliding surface is largely covered by a graphite film.



Base alloy/ composite	Material	Graphite content, %	Pressure		Ref
			MPa	ksi	
○/•	Al-12Si	15	0.4	0.06	46

Fig. 16 Wear rate as a function of sliding speed for aluminum alloy composites containing graphite particles

Effect of Contacting Conditions. In general, composites that contain soft particles are tested only under sliding wear conditions, and composites that contain hard particles are tested under various conditions, including sliding, rolling and abrasive wear.

Sliding wear conditions are based on differences in the nature of relative movement between surfaces: reciprocating and rotational. Abrasive wear can be divided into two-body abrasive wear, such as rotation against a ceramic disk or ceramic particle coatings, and three-body abrasive wear, such as RWAT with ceramic particles fed between the specimen and the rotating rubber wheel.

For the same material, different contacting conditions will affect the wear result and even the wear mechanisms (Ref 75). Pan *et al.* (Ref 12) have reported that for aluminum alloy composites containing 15% ceramic particles, the specific wear rate under rolling contact is higher than that under sliding contact, as shown in Table 5. The wear rate under abrasive wear for the same matrix alloy is also included in Table 5 for reference. In rolling contact, the roller is subjected to a cyclic stress, and thus fatigue failure appears to be the dominant wear mechanism. The material is removed by debonding and the removal of ceramic particles, and by the formation of fatigue cracks at pitting spots on the rolling surface (Ref 12).

Table 5 Effect of contact conditions on wear rate in aluminum alloy hard-particle composites

Composite		Normal load, N	Sliding speed, m/s	Specific wear, $mm^3/m \cdot N$

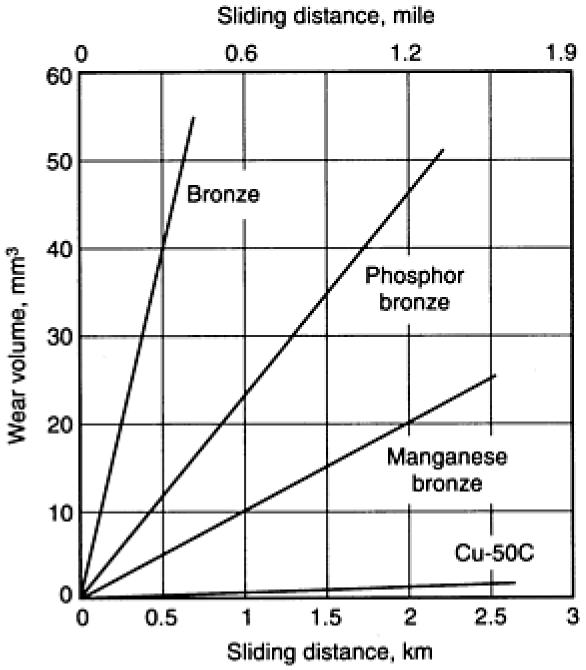
Tribological Behavior of Fiber-Reinforced Metal-Matrix Composites

Adhesive Wear Conditions. Figure 17 shows the wear volume for dry reciprocating sliding wear, as a function of sliding distance, in different copper alloys and copper-carbon continuous-fiber composites, with the fibers aligned perpendicular to the sliding surface. Compared with the copper alloys, the copper composite containing 50% reinforced carbon fibers exhibits a significantly lower wear rate (Ref 76).



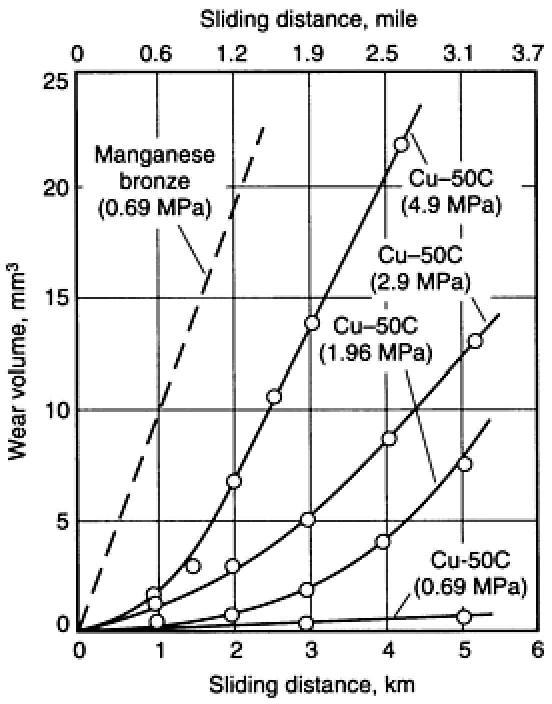


Fig. 17 Wear behavior of copper alloys and copper-carbon fiber composites. (a) *P* = 0.69 MPa (0.1 ksi). (b)

0.69 MPa ⩽P ⩽4.9 MPa (0.1 ⩽P ⩽0.7 ksi)

The effect of volume fraction of carbon fibers on the friction and wear behavior of copper alloy composites is shown in Fig. 18. The friction coefficient and wear rate decrease when the volume fraction increases from 30 to 40%. Similar wear results have been reported for aluminum alloy composites containing SiC whiskers (Fig. 19). Wear is reduced as the volume fraction of SiC whiskers increases from 0 to 20%; up to 40 vol% SiC, further decrease in wear is small. Although there is a wide scatter in the wear results for fiber-reinforced metal-matrix composites, wear resistance of metals or alloys can be improved by the introduction of a proper amount of fibers (Ref 76, 77, 78, 79, 80, 81, 82, 83). The effect of volume fraction of fibers on the coefficient of friction is less clear. It appears that the coefficient of friction tends to decrease with increase in volume fraction of graphite in copper-graphite composites (Fig. 18), but friction increases with whisker content in aluminum alloy composites that contain SiC whiskers (Fig. 19). Testing parameters also affect the wear rate of fiber-reinforced metal-matrix composites. Wear rate increases with an increase in normal load (Ref 76, 82, 83), and there is a transition from mild to severe wear at a critical load, as observed in Al-20SiC whisker composites (Ref 78). A similar transition has been reported in copper-carbon fiber composites, depending on the volume fraction of fibers (Ref 76).

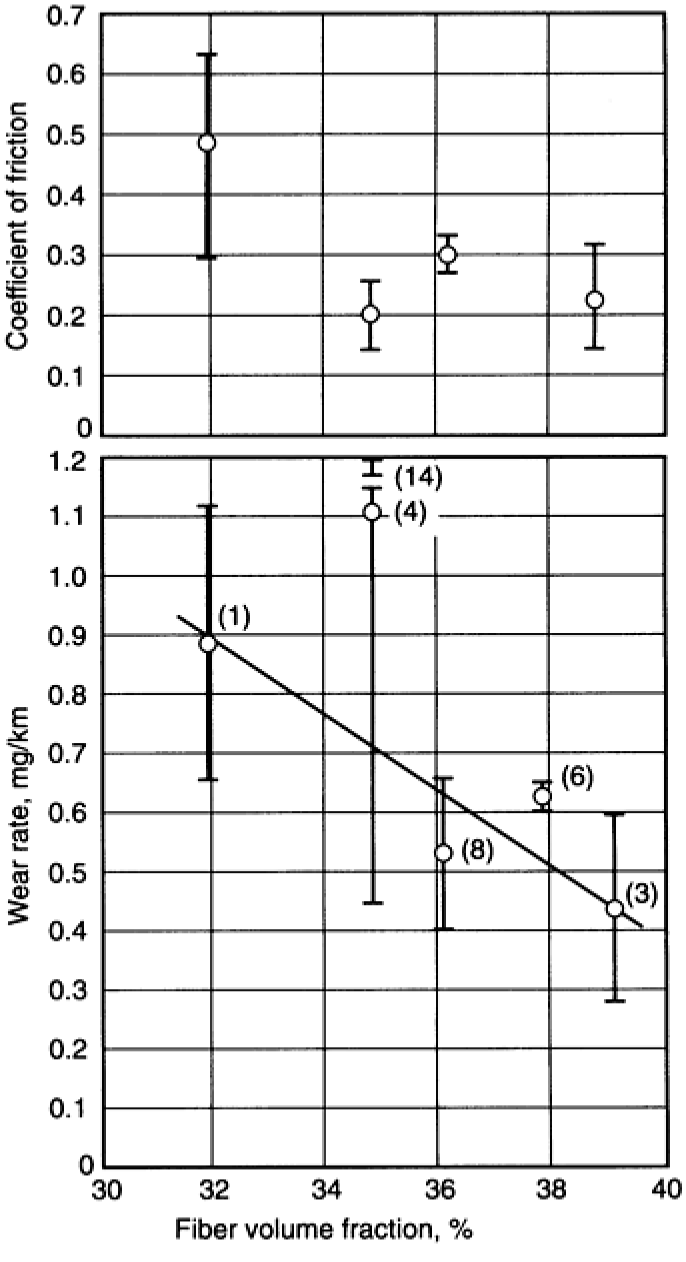

Fig. 18 Effect of fiber fraction on wear and friction of Hm3000/bronze carbon fiber. Numbers in parentheses

indicate tin content of bronze matrix.

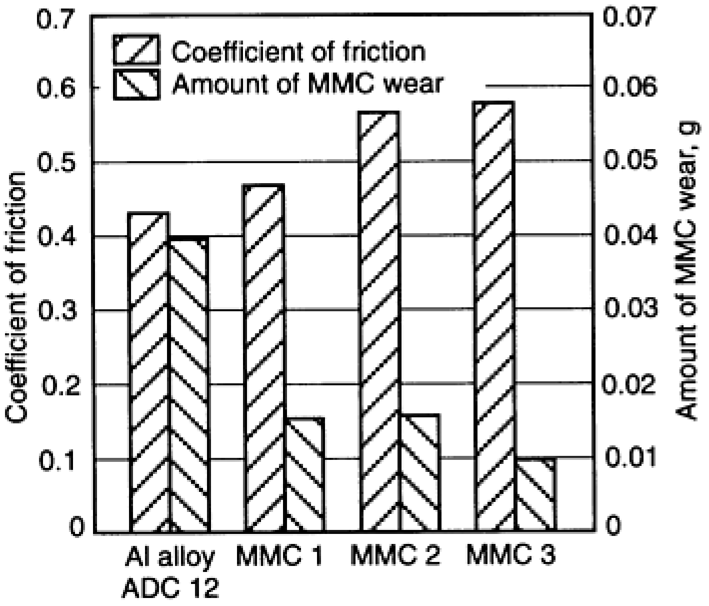

Fig. 19 Friction and wear characteristics of metal-matrix composites (MMC) on steel. The composites all had an ADC 12 matrix and were reinforced with the following volume fractions of SiC whiskers: 20% (MMC1), 30% (MMC2); 40% (MMC3). Test conditions: sliding velocity, 2 m/s; pressure, 0.1 MPa (0.015 ksi); duration, 1 h

Abrasive Wear Conditions. Recently, Verma and Dorcic (Ref 84) reported that the abrasive wear resistance of aluminum alloy A206 with discontinuous fibers of Al_2O_3 and SiO_2 is comparable to induction-hardened AISI 1345 steel (Table 6). The tests in Table 6 were performed using a dry sand/rubber wheel abrasion machine (ASTM Standard G65-B). Further studies are needed to determine general trends in the abrasive wear behavior of fiber-reinforced composites.

Table 6 Comparison of wear rates of AISI 1345 and squeeze-cast composites

Material	Specimen no.	Initial weight, g	Final weight, g	Weight loss, g	Average weight loss, g	Average volume loss, mm
AISI 1345	1	114.4135	114.1204	0.2931	0.2779	35.4
	2	114.3513	114.0807	0.2706		
	3	114.3439	114.0739	0.2700		
A206-T7 + ceramic foam	1	43.7071	43.0129	0.6942	0.6885	242.00
	2	48.0881	47.4054	0.6827		

Effect of Fiber Type and Orientation. Graphite fibers from different precursors affect the friction and wear behavior of fiber-reinforced metal-matrix composites (Ref 80, 83), as shown in Table 7. The effect of fiber orientation on friction and wear is shown in Fig. 20. For copper alloy composites containing 50% carbon fiber, wear volume increases with sliding distance for any fiber orientation. However, the wear volume in composites with randomly arranged fibers is extremely low (Fig. 20), and the wear volume of composites with fibers vertical to the sliding surface is lower than that of composites with fibers parallel to the sliding surface. This finding is supported by results obtained by Eliezer and co-workers (Ref 80). Amateau *et al.* (Ref 83) have shown that the orientation of fiber did not significantly affect the wear rate and coefficient of friction of aluminum alloy composites containing graphite fibers. Although experimental results appear to be contradictory for different systems, it is generally believed that fiber orientation affects wear results, not only for metal-matrix composites but also for polymer-matrix composites. It appears that lower wear rates and coefficients of friction are obtained in composites with fibers arranged randomly or normal to the sliding surface; for composites with fibers parallel to the sliding surface, however, friction and wear also depend on fiber orientation relative to sliding direction.

Table 7 Effect of graphite fiber precursor on friction and wear in aluminum alloy composites

Composite		Precursor	Wear rate[(a)], 10^{-14} m^3/s	Coefficient of friction

	Thornel 300	PAN	7.1	0.48
A16061	Thornel 50	Rayon	36.2	0.25
	Thornel 75	Rayon	32.9	0.25
	Hercules A	PAN	3.1	0.52

(a) Tests were conducted at a load of 6 N, a linear sliding speed of 0.684 m/s, and a sliding time of 6 min.

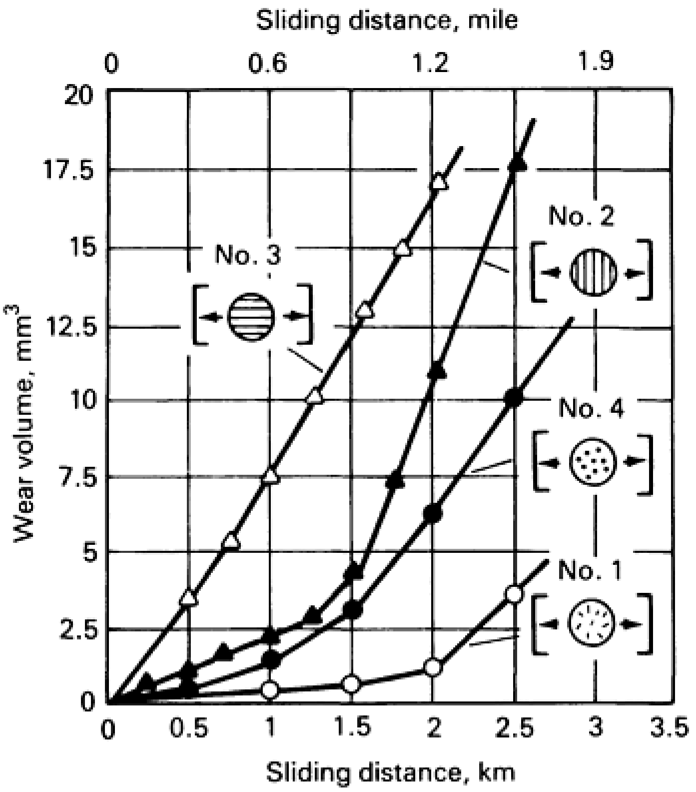

Fig. 20 Effect of sliding direction and fiber arrangement on wear volume of copper-carbon composite. *P* = 4.9 MPa (0.7 ksi)

Kuniya *et al.* (Ref 76) have explained the effect of fiber orientation in copper-base composites. They presumed that because of weak bonding between the fibers and the matrix, the fibers easily debonded when parallel to the sliding direction. Arikan and Murphy (Ref 85) have observed similar behavior in metal-matrix composites with randomly dispersed fibers. Fibers parallel to the wear surface are easily debonded and removed during wear testing, but fibers perpendicular to the wear surface break off in small sections.

Wear Mechanisms

Mechanisms of Sliding Wear in Metal-Matrix Composites Containing Hard Particles. You and co-workers (Ref 86) have reported three different stages of wear in aluminum alloy A2024 base composites that contain 20% SiC particles, when sliding against a steel counterface. Scanning electron microscopy (SEM) reveals these three stages: (1) formation of steel filings (steel debris) on the testing pin, caused by microcutting of the counterface by SiC particles; (2)

packing of the filings on the sliding pin surface between particles; and (3) gross pin surface deformation with loss of SiC particles. The onset of steady-state wear is associated with the end of the second stage or the beginning of the third stage. A transfer layer--a mixture of iron debris, SiC fragments, and aluminum matrix debris--forms on the sliding surface of the pin under steady-state wear. A high level of strain in the subsurface region with a high density of dislocations has been observed up to a depth of 150 μm. The formation of a transfer layer on the sliding surface has been reported by Keshavaram *et al.* (Ref 35) in aluminum alloy composites containing glass particles, by Murali *et al.* (Ref 24) in aluminum alloy composites containing char, and by Nath and Rohatgi (Ref 17) in aluminum alloy composites containing mica particles. Observations by SEM suggest that the debonding of particles is not a dominant mechanism of sliding wear (Ref 16, 20, 85). However, the formation of a transfer layer results in grinding of the sliding surface by a mixture of this layer.

A wear model has been proposed that is based on an adhesive wear mechanism (Ref 76, 78, 80) and on the assumption that each phase of a composite (matrix and particle) wears out independently and contributes to the overall wear rate (Ref 56):

$$K_c = K_m f_m + K_p f_p \quad \textbf{(Eq 1)}$$

where K is the wear coefficient, f is the volume fraction, and the subscripts c, m, and p represent composite, matrix, and particle, respectively. Because the value of K_p is likely to be several orders of magnitude lower than K_m under experimental conditions, Eq 1 can be simplified to:

$$K_c = K_m f_m = K_m(1 - f_p) \quad \textbf{(Eq 2)}$$

This model does not explain the effect of particle hardness, which has been identified as a very influential factor in wear, and should be modified to include the active role of particles in reducing wear, as evident in Fig. 5 for composites containing SiC and Al_2O_3. Considering the hardness of particles, a modified equation has been proposed:

$$K_c = -\alpha f_p + K_m \quad \textbf{(Eq 3)}$$

where α is the coefficient factor and can be obtained from the slope of the wear curves.

Mechanisms of Abrasive Wear in Composites Containing Hard Particles. Abrasive wear usually can be classified on the basis of the nature of interactions, such as two body or three body. For two-body abrasive wear, Saka and Karalekas (Ref 57) have shown that a delamination model is feasible for copper-base hard-particle composites, as shown in Fig. 21. In this model, wear resistance is strongly dependent on fracture toughness and not merely on composite strength, because crack propagation is the controlling factor (Ref 58, 59, 60).

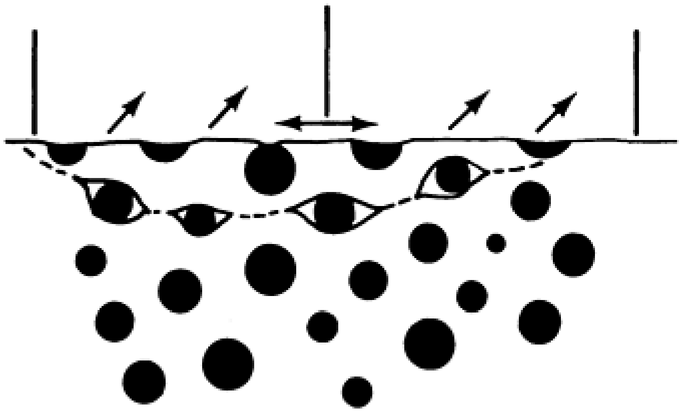

Fig. 21 Schematic diagram showing the delamination process in abrasive wear of metal-matrix composites containing hard particles

In three-body abrasive wear, abrasive particles such as silica sand tend to break down and bury themselves in alloys with relatively soft matrices. Very fine silica particles trapped below scratches have been observed under SEM (Ref 51). However, hard particles in composites resist scratching because of their high hardness under low loads and crack into small pieces under heavy loads. The broken particles remain embedded in the matrix during wear. In this case, composite strength and fracture toughness both play important roles. Similar results have been observed by Yang and Chung (Ref 16) for aluminum alloy composites that contain bauxite particles. Some investigators report that micromachining is still the dominant mechanism of material removal during abrasion wear in composites. Removed chips in the debris are approximately the same size as the hard particles.

Mechanisms of Sliding Wear in Composites Containing Soft Particles. A typical composite in this group is the metal-matrix/graphite-particle composite. The wear mechanisms in composites containing graphite particles are discussed in detail in Ref 45. Similar systems include composites containing dispersoids such as MoS_2 and PTFE. Formation of a lubricating film on the tribosurface is considered to be responsible for the low friction and wear of composites belonging to this group. The area covered by a lubricating film, which is related to the volume fraction of soft particles, is the controlling factor. Tsuya (Ref 41) has measured the concentration of MoS_2 in the solid lubricating film formed during sliding wear in the Cu-MoS_2 system as a function of the volume fraction of MoS_2 in the composite (Fig. 22). More than 60% of the sliding surfaces is covered by MoS_2 during adhesion wear testing in Cu-20MoS_2 composites, and more than 40% of the sliding surfaces is covered by MoS_2 in Cu-10MoS_2 composites. These results are in general agreement with Auger electron spectroscopic observations of aluminum alloy composites containing 10% graphite (Ref 42).

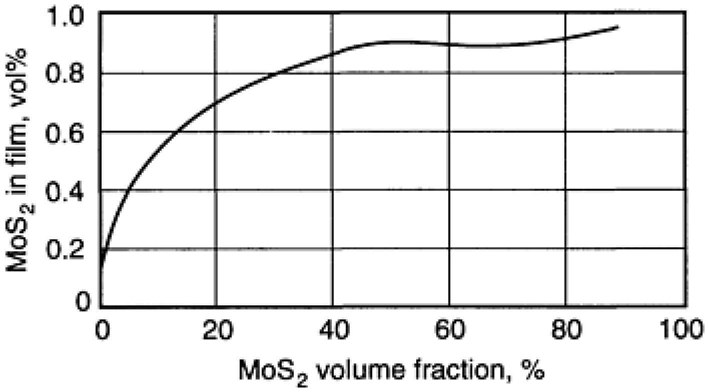

Fig. 22 Concentration of MoS_2 in the surface film formed during sliding as function of MoS_2 volume fraction for copper-base composites. Source: Ref 41

Conclusions

Metal-matrix particle composites have been classified into two groups: those containing hard particles with hardnesses in the range of 4 to 30 GPa (580 to 4350 ksi) and those containing soft particles with hardnesses less than 2 GPa (290 ksi). The tribological properties and relevant mechanical properties which influence wear and friction have been summarized and discussed for these two groups. The main conclusions that can be reached include the following:

- The ultimate tensile strength (UTS) of metal-matrix composites increases with an increase in volume fraction of hard particles, and decreases with an increase in volume fraction of soft particles. The fracture toughness and ductility of composites decrease with the increase in the volume fraction of both hard and soft particles
- Under sliding wear against a steel counterface, the wear rate of metal-matrix composites decreases with an increase in volume fraction of either hard or soft particles if the bonding between the matrix and the particles is adequate
- The coefficient of friction of the composites under sliding wear can be roughly divided into three ranges: In range I, the coefficient of friction of the composites containing hard particles is between 0.3

and 0.5 and is close to that of the base alloys; in range III, the coefficient of friction of composites containing soft particles is between 0.1 and 0.3 and is similar to the coefficient of friction of the soft particles if the volume fraction of soft particles is over 20%. The friction coefficient of composites containing particles of intermediate hardness is in range II, which is intermediate between ranges I and III

- Formation of a solid lubricating film during sliding wear has been considered as the primary factor responsible for low wear and friction in composites containing soft particles of solid lubricating materials
- Under abrasive wear, the wear rate of aluminum-base composites containing hard particles usually decreases with an increase in volume fraction of particles
- The erosive wear rate in iron- and cobalt-base composites increases with carbide particle content when tested with quartz erodent
- The wear rate is inversely proportional to the particle size in composites containing either hard or soft particles, under either adhesive or abrasive wear conditions
- The wear rate increases with normal load in hard-particle composites under adhesive or abrasive wear. For composites containing higher amounts of soft particles, the wear rate tends to decrease with increasing load up to a critical value before severe wear sets in
- Variations in contact conditions affect wear results. In addition, the relative orientation of the fiber and the sliding direction are important parameters influencing wear
- For metal-matrix composites containing hard particles, sliding against a steel counterface results in generation of steel filings due to microcutting; these filings are compacted during sliding to form a transfer layer
- Under abrasive wear, delamination and micromachining mechanisms are responsible for wear in composites containing hard particles under both two-body and three-body wear conditions

Friction and Wear of Ceramics

W.A. Glaeser, Battelle Memorial Institute

Introduction

CERAMICS, which are inert nonmetallic solids, and cermets, which are metallic bonded ceramics, have been used for tribological purposes for decades. Although high manufacturing costs have limited their applicability, they have been used in special applications, such as high-temperature or highly corrosive environments, and in situations that require high resistance to wear. The toughened ceramics and fiber-reinforced composites that have recently been introduced have opened up new areas of applicability.

The general class of ceramics (that is, pottery, tiles, bricks, toilets, insulators, and porcelains) can be divided into two product lines:

- Fired clays consisting primarily of small crystals of hydrated aluminosilicates
- Expensive high-tech pure dense oxides, nitrides, carbides, and borides

These high-tech products are used in tribological applications. Whereas the fired clays consist of heterogeneous mixtures of crystals embedded in a glassy matrix, the high-tech ceramics are derived from manufacturing abrasives. These crystalline abrasive materials are refined from the impure grit into high-purity products and are compacted into solids which approach the theoretical density of the material and have very little, if any, glassy binder. The porosity of high-tech ceramics is less than 0.5%, much less than the 5 to 15% porosity present in traditional ceramics. The improvement in structural properties of ceramics continues and is typified by the development of hot isostatically pressed (HIP) silicon nitride balls for applications such as high-precision machine tool bearings.

Applications

Ceramics are used for high-temperature bearings and in very aggressive environments. They are also being substituted for conventional metal alloys in some applications. Examples of current application areas are described below.

Bearings. Sapphire is used for jewel bearings in watches and instruments, whereas silicon nitride is used in some ball bearings, as well as in high-temperature heat engines.

Mechanical Seals. Alumina and silicon carbide are used as seal rings in face seals and floating ring seals, particularly in corrosive and erosive fluids. They are applied in oil fields, the chemical processing industry, and pumps.

High-speed machine tools utilize ceramics because of their resistance to heat, which enables deeper cuts and the use of higher cutting speeds than conventional high-speed steel tools. Silicon nitride, Sialon, Alumina, whisker-reinforced alumina, and titanium carbide/nitride are examples of ceramics that are used for cutting tools. Ceramic tools can successfully and rapidly cut cast iron, which can be very abrasive to ordinary tools.

Guides and Rollers. Alumina is used in the textile industry as the fiber guide for high-speed thread spinning. It is also used for computer tape guides and capstans. Silicon nitride is used for the rollers in furnace conveyors, such as those used in metal heat treating and porcelain firing.

Wear plates made of alumina are used in the handling of abrasive materials, such as coal, ash, and slurries, which are found in coal slurry pumping systems and in cyclones that separate coal and water prior to burning. Paper-handling machinery also utilizes ceramic components.

Advanced Heat Engines. Low-heat-loss engines that can conserve fuel are being designed with ceramic (silicon nitride) cylinders, valves, and piston rings. The intent is to operate at a combustion temperature that is much higher than that of conventional engines and to approach adiabatic conditions. Ceramic parts are also being introduced into engine design to reduce wear.

Medical prostheses that utilize alumina ceramics include bones, joints, and tooth roots.

Ceramic dies made of alumina, zirconia, or Sialon are used for some metal extrusion and drawing applications to provide smoother product surface finishes and longer die life.

Mechanical and Physical Properties

The properties of select commercial ceramics that are typical of those used in tribological applications are given in Table 1. A tool steel is included for comparison purposes. The values given in Table 1 are primarily intended to indicate averages of property levels, rather than actual values. Mechanical values vary in the literature, because ceramics properties are significantly influenced by manufacturing processes. Thus, one grade of ceramic can vary in hardness and toughness, depending on its manufacturer. Important data, such as thermal shock resistance, flexural strength, creep at elevated temperatures, and oxidation or decomposition data, are available only for certain types of ceramics.

Table 1 Typical mechanical and physical properties of generic ceramics

Property	Al_2O_3	SiC	Si_3N_4	PSZ	Sialon	TiC	WC/Co	Pyrex	Steel (01 grade, heat treated)
Density, g/cm^3	3.9	3.1	3.3	5.8	3.2	4.9	3	2.5	7.86
Thermal conductivity, W/m · K (Btu/ft · h · °F)	35.6 (20.6)	126 (73)	27 (16)	1.8 (1.0)	21 (12)	35 (20)	1.6 (0.9)	1.5 (0.87)	51.9 (30.1)
Coefficient of thermal expansion, μm/m · °C	7.1	4	2.3	10.1	3	8	6	5	12.1
Heat capacity, J/kg · K	880	2800	810	400	620	600	. . .	500	448
Hardness, HV · kgf/mm^2	1500	2700	1300	1600	1780	3000	1500	. . .	600
Young's modulus, GPa (10^6 psi)	370 (55)	410 (60)	276 (40)	200 (30)	290 (42)	430 (62)	552 (80)	70 (10)	200 (30)
Tensile strength, MPa (ksi)	262 (38)	100 (15)	524 (75)	700 (102)	450 (65)	896 (130)	896 (130)	. . .	2000 (290)
Compressive strength, MPa (ksi)	2600 (380)	. . .	. . .	1850 (270)	3500 (510)	. . .	. . .	. . .	. . .
Flexural strength, MPa (ksi)	380 (55)	550 (80)	660 (95)	690 (100)	. . .	250 (36)	250 (36)	69 (10)	. . .
Fracture toughness, MPa$\sqrt{\text{m}}$ (ksi$\sqrt{\text{in.}}$)	. . .	4.6 (4.2)	4.5 (4.1)	9.5 (8.6)	7.7 (7.0)	. . .	. . .	. . .	14 (12.7)
Poisson's ratio	0.26	0.19	0.24	0.23	. . .	0.19	. . .	0.2	0.3
Melting point, °C (°F)	2015 (3660)	2700 (4890)	1900 (3450)	2700 (4890)	. . .	. . .	. . .	. . .	1600 (2910)

As shown in Table 1, the hardness of ceramics is significantly higher than that of hardened tool steel, whereas ceramic density is lower. The ceramics also have greater strength values than does steel. Many of the ceramics listed in the table are also stiffer than steel and therefore should have greater beam strength per square unit cross section. Furthermore, the lower Poison's ratio and higher Young's modulus of ceramics (versus steel) results in higher contact stresses and smaller contact areas for Hertzian contacts formed on ceramic balls or rollers in bearings, for instance.

Another desirable property that can be achieved in ceramics is hot hardness, which is valuable in high-temperature applications. The hardness-temperature characteristics of ceramics and metallic tool materials are shown in Fig. 1, which indicates the advantage of using ceramics and sintered carbides, versus the use of high-speed steels. Ceramic tools are being used increasingly in manufacturing environments. The coating of sintered carbide tools with TiN (Ref 1, 2) has been an important improvement in tool endurance.

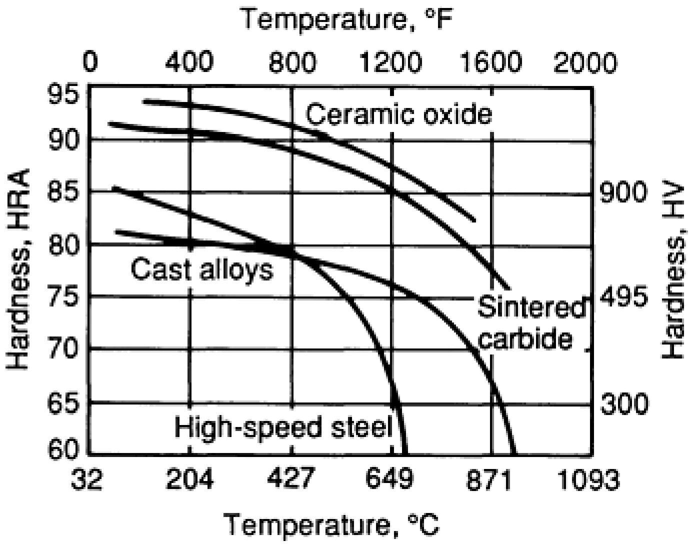

Fig. 1 Hot hardness of tool materials and steels

A large percentage of commercial products are not pure oxide or carbide ceramics. Rather, they are cermets, which are powders bonded by metals or glassy materials. Tungsten carbide and titanium carbide, for example, are generally bonded with cobalt or nickel. The percentage of bonding material in various grades of these cermets will influence their hardness, toughness, thermal conductivity, and abrasion resistance. The effect of cobalt content on tungsten carbide is shown in Table 2. Principally used in tools and rock drilling bits, the cermet metal binder content is adjusted for the potential application. Therefore, it is best to obtain data on properties for a given grade from the manufacturer.

Table 2 Effect of cobalt content on tungsten carbide properties

Cobalt, wt%	Hardness, Rockwell A	Transverse rupture		Young's modulus		Coefficient of thermal expansion	
		MPa	**ksi**	**GPa**	**10^6 psi**	**μm/m · K**	**μin./in. · °F**
3	92.7	1207	175	0.72	0.10	3.0	5.5
6	92	1517	220	0.72	0.10	3.1	5.7
9	89.3	1572	228	0.61	0.09	3.9	7
12	86.8	2069	300	0.58	0.08	4.1	7.5
16	86.8	2503	363	0.52	0.075	4.4	8
25	84.5	2586	375	0.48	0.07	6.1	11.1

As noted previously, ceramics are ideal materials for high-temperature applications that can justify their cost. For example, the hot hardnessvalue of silicon nitride is retained to about 1200 °C (2190 °F). However, some ceramics (other than the oxides) can degrade at elevated temperatures. The carbides and nitrides are subject to oxidation. Those that contain silicon, such as silicon carbide and silicon nitride, depend on a film of silicon dioxide to protect their surfaces from oxidation. Above 1500 °C (2730 °F), the film softens, oxygen diffuses into the bulk material, and unacceptable oxidation of the body occurs. At elevated temperatures, alumina and zirconia, which are fully oxidized, will not oxidize, although the glassy binder in alumina tends to soften, and partially stabilized zirconia undergoes phase changes.

Perhaps the greatest drawback to using ceramics in machinery is their brittleness, or low toughness. Even when advanced toughening techniques are applied, they still fall short of requirements. Ceramics have not yet found acceptance in gas

turbine engines (Ref 3), although operating temperatures have continually increased in new designs. Instead, superalloys are still used with elaborate cooling systems.

The major obstacle to the use of ceramics in advanced gas turbines is an unacceptable fracture toughness. Levels for candidate ceramics and superalloys are shown in Fig. 2. Note that even the toughened ceramics fall below the required maximum fracture toughness level. The advanced low-heat-loss diesel engine, once considered a good candidate for ceramics, has not yet gone into production. High friction losses and thermal shock problems need to be overcome.

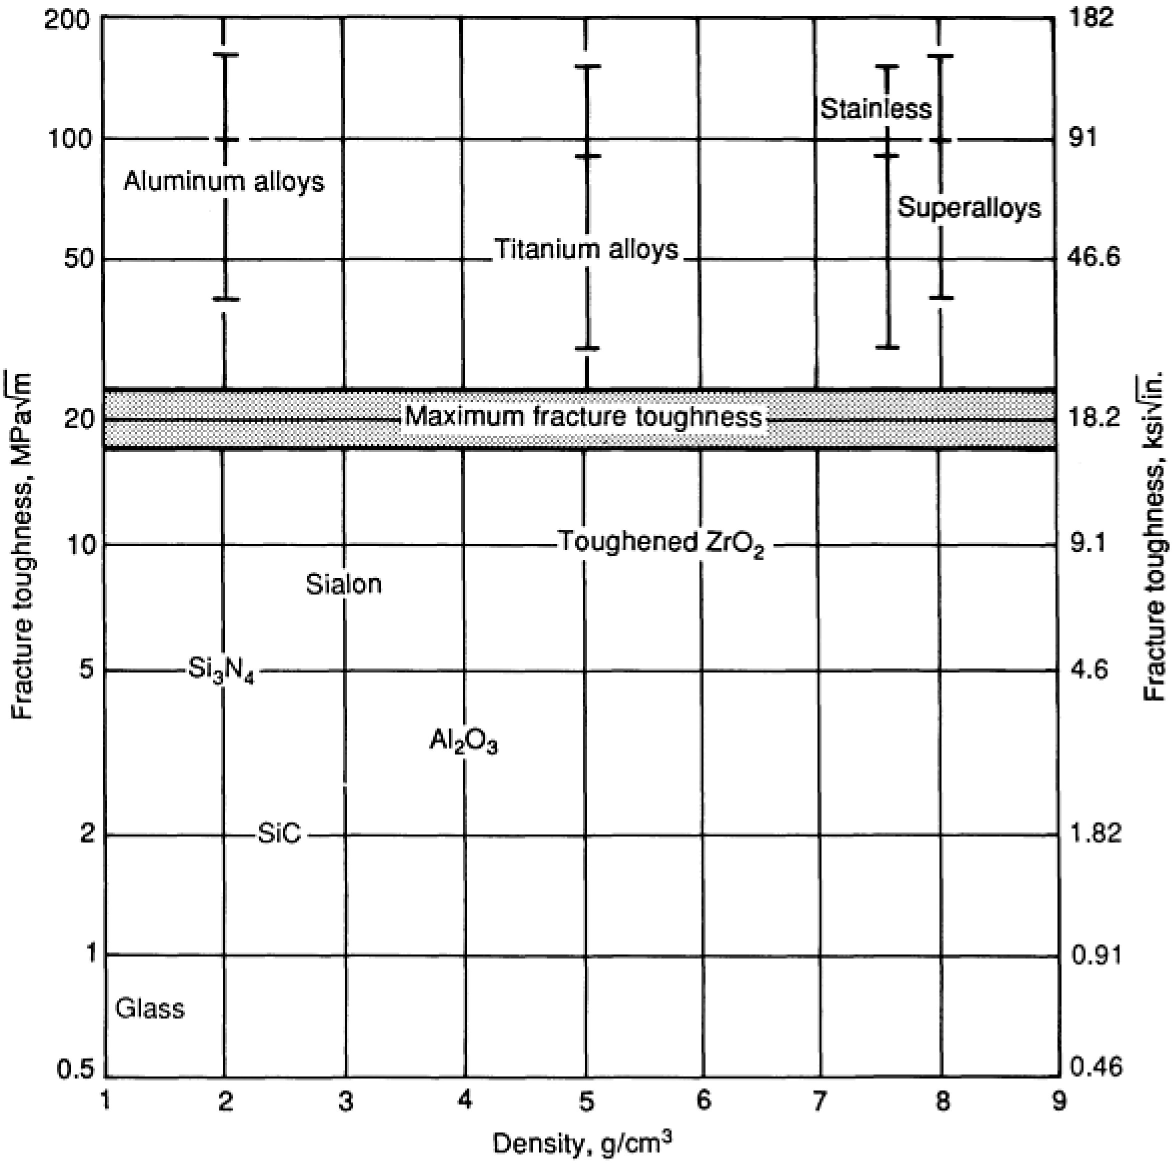

Fig. 2 Comparison of fracture toughness of selected ceramics. Source: Ref 3

Ceramics are being used to a limited extent in heavy-duty diesels, as fuel injector system components. Cam follower rollers represent another development. Both applications utilize silicon nitride. Water pump seals made of silicon carbide are also widely used.

Wear Properties

Because of their inherent brittleness, ceramics can wear by chipping. Surface and subsurface cracks form, join, and release small chips of material. A fine powder is produced as this wear debris is ground up in the wear process. Therefore, ceramics are sensitive to high contact stresses or to any contact condition leading to a state of stress that contains tensile

components. Metals and plastics can deform plastically to relieve high contact stresses before fracture occurs. Ceramics can deform plastically under the hydrostatic stress associated with concentrated contacts, but the plastic deformation involved is very small, when compared with metals and polymers.

Increasing the temperature of a ceramic material to about 0.6 times the melting point, T_m, increases the mobility of dislocations and increases the potential for plastic deformation. Strength reduction and increased creep rates also accompany the rise in temperature. However, the increase in plasticity with increase in temperature does not produce the ductility that is common in metals. Either a brittle or semi-brittle behavior persists.

In instances of sliding contact, brittle materials can exhibit deformation-type wear. In cases of either abrasion or erosion, wear behavior is much different. Both abrasive and erosive processes involve tensile components in the contact state of stress. For abrasive wear, the wear rate is proportional to the elastic modulus and inversely proportional to hardness and fracture toughness. However, it has been shown that alumina and silicon carbides also exhibit a sensitivity to microstructure during wear by scratch tests (Ref 4). The grain size and properties of the intergranular material were found to influence wear.

The thermal-shock-induced fracture of ceramics is a serious wear problem. Because of low thermal conductivity, large thermal gradients can develop in ceramics during frictional heating. When quenched, these hot spots develop large tensile stresses and cracks develop. The result is an increase in wear as relatively large pieces break out of the surface. Eventual failure by fracture can occur.

Ceramics are sensitive to strain rate and will exhibit an increased tendency to crack with increased sliding velocity, in addition to the frictional heating. This sensitivity to impact makes ceramics vulnerable to erosive wear. The angle of impingement of solid-particle erosion influences the rate of material removal. For metals, maximum erosive wear occurs at an impingement angle between 20° and 40°. Ceramics, on the other hand, show high erosive wear when the erosive particle angle nears 90°. Figure 3 shows the difference in erosion rate versus impingement angle for ceramics and metals.

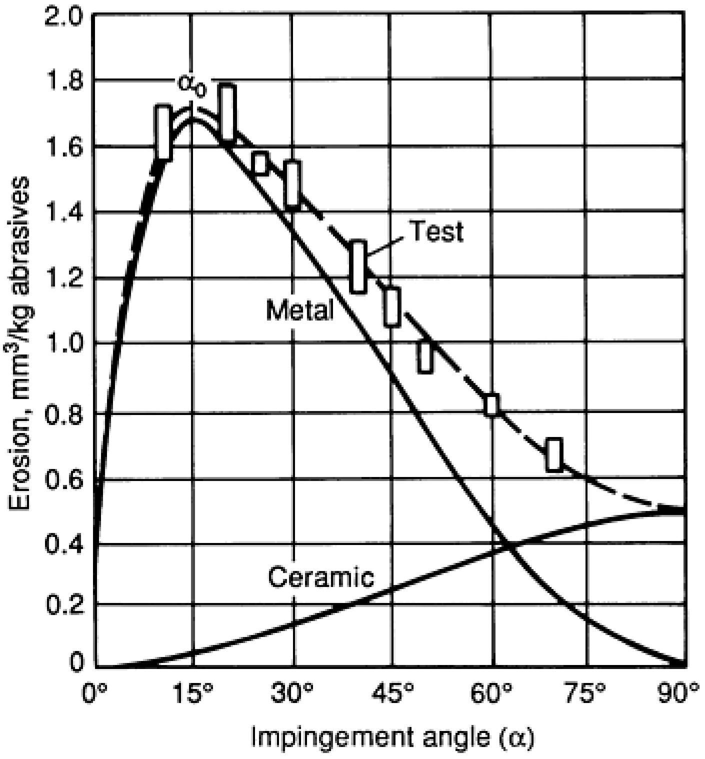

Fig. 3 Effect of erosion impingement angle on material removal rate for ceramics and metals.

The relative hardness of the ceramic and eroding medium is important to erosion mechanisms. When the erodant is either softer or about as hard a the ceramic, a small increase in its hardness causes a large increase in erosive wear. When the

erodant is much harder than the ceramic, microstructure and fracture toughness become more important to the rate of erosion (Ref 5). Thus, a hard ceramic will resist particle erosion as long as the erodant is much softer than it is. if the erodant is harder than the ceramic, then the erosion rate can be minimized by providing as much toughness as possible, a small grain size, and minimum porosity.

Heat-Treatable Ceramics

Transformation-toughened ceramics have been a relatively recent development in which the fracture toughness of certain ceramic "alloys" has been enhanced by taking advantage of phase transformations. Zirconia, in particular, can exist in three different crystal structures: cubic, tetragonal, and monoclinic. The important aspect of this polymorphism is the change in density that accompanies phase transformation. Although zirconia-toughened ceramics are numerous, Y_2O_3 and MgO partially stabilized zirconia (PSZ) are the most developed and most often used materials. Because zirconia has a very high melting point (2850 °C, or 5160 °F), it is potentially a high-temperature structural material. When alloyed with MgO, the phase diagram shown in Fig. 4 (Ref 6) indicates that the structure can be manipulated by heat treatment in a manner similar to that used for metal alloys.

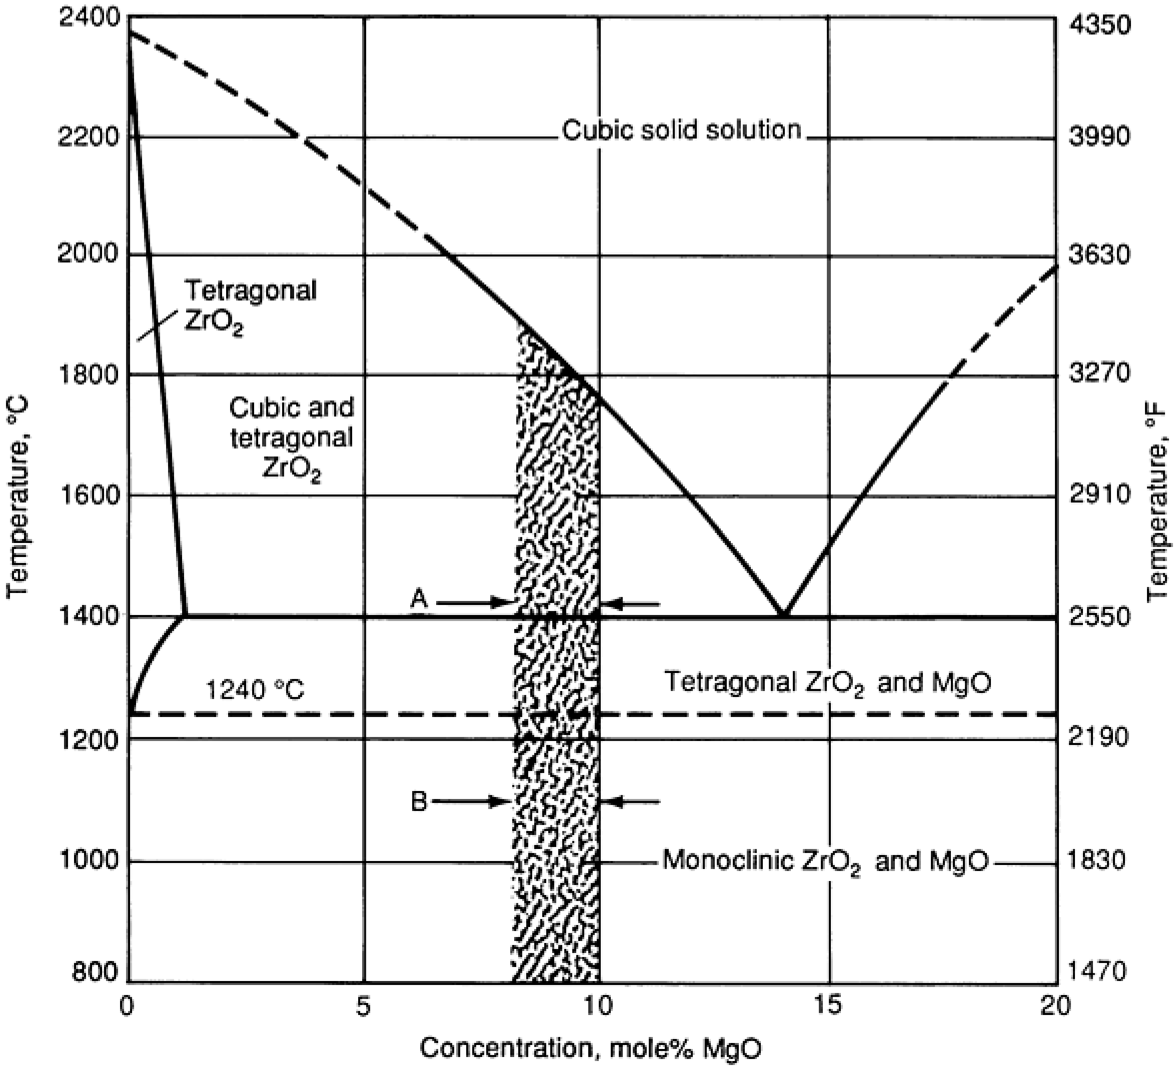

Fig. 4 Zirconia MgO phase diagram. The shaded region indicates the composition range used in most commercially available alloys. Aging is carried out at temperatures above the eutectoid temperature at A to obtain maximum strength and below the eutectoid temperature at B to obtain maximum thermal shock resistance.

The most common MgO-zirconia compositions fall in the shaded range of Fig. 4. The "stabilization" of zirconia, through the addition of MgO, Y_2O_3, or CeO_2, lowers the cubic-to-tetragonal transformation temperature. Without the added stabilizers, this transformation results in tensile stresses and microcracking. Thus, stabilization allows the sintering of zirconia powders in the cubic phase and cooling to room temperature without any phase transformation. Because the transformation shown in Fig. 4 is very sluggish, precipitation hardening is possible. Heating the sintered body to 1800 °C (3270 °F) and then quenching, followed by reheating and annealing at 1400 °C (2550 °F), results in the precipitation of tetragonal particles. If the tetragonal phase is coarsened such that it becomes metastable, then it will transform to the monoclinic phase when stressed by a nucleating crack, and will inhibit crack propagation by producing a compressive field at the crack tip. The heat-treatable zirconia is known as partially stabilized zirconia, which retains hardness and wear resistance while acting as a tougher material.

It has been suggested that frictional heating during sliding contact can also produce phase changes in PSZ (Ref 7). Frictional heating can achieve temperatures that are high enough to transform the monoclinic phase to tetragonal, or even to cubic, resulting in a volume reduction and tensile stress cracking.

Aluminum-oxide ceramics and mullites (alumina-silica) can be toughened by the addition of zirconia (Ref 8), and have been used as advanced tool materials. Other such materials include silicon carbide whisker-reinforced alumina and modified Sialons (Ref 9).

Although zirconia can be toughened and thus successfully used in cam and tappet assemblies, cutting tools, and dies, it is susceptible to thermal shock. Its thermal expansion coefficient is high, and its thermal conductivity is low, which makes it more sensitive to thermal shock than silicon nitride, for example. Thermal diffusivity, or the ability to dissipate temperature gradients rapidly, is low in this material and is affected by thermoelastic instability, as are other low-diffusivity ceramics, such as magnesia and alumina. During sliding contact tests that simulated piston ring-cylinder sliding contact under diesel operating conditions, it was shown that PSZ exhibited classic thermoelastic instability (Ref 10). Self-mated yttria-PSZ that ran dry operated at a high friction coefficient and had a high level of wear, because of thermal shock induced by localized frictional heating.

A critical sliding velocity exists for each material, above which thermoelastic instability (TEI) initiates. An equation has been developed to predict the critical velocity, V_{cr}, for various materials, using their thermal properties (Ref 11). A simplified expression is:

$$V_{cr} = \frac{4K^2}{(\mu \alpha E)^2 \pi k z} \quad \textbf{(Eq 1)}$$

where V_{cr} is the critical sliding velocity, K is thermal conductivity, μ is the coefficient of friction, α is the coefficient of thermal expansion, E is Young's modulus, k is thermal diffusivity ($K/\delta c$ where δ is density and c is specific heat), and z is the width of the slider.

The velocity used in the simulated engine tests was 5.4 m/s (18 ft/s). The coefficient of friction for yttria-PSZ was 0.13, and the estimated V_{cr} was 8.9. For silicon nitride, the coefficient of friction was 0.08, and the estimated V_{cr} was 538. The silicon nitride performed without evidence of TEI.

Rolling Contact Bearings

High-speed ball bearings become subject to a higher incidence of rolling contact fatigue damage as speeds increase. This is the result of centrifugal force between the balls and the outer races. Advanced high-speed gas turbines are limited in performance by this effect. By using a less-dense ball material, such as silicon nitride, this effect can be reduced. It has been demonstrated that five-ball rolling contact tests indicated that low-mass silicon nitride balls performed as well as bearing steel balls (Ref 12). In other words, the fatigue life of hot-pressed silicon nitride balls in the five ball apparatus was equal to that of typical bearing steels.

More recently, continuing development of silicon nitride components in ball bearings for applications such as gas turbines and high-speed spindles for machine tools continue to show promise as solutions for the extreme operating demands of these components. Hybrid bearings having silicon nitride balls and tool steel races have been developed for very high-speed applications. The centrifugal loads on the outer races that result from steel balls used in high-speed bearings can be

reduced by using lower density silicon nitride balls. Endurance tests conducted on these hybrid bearings have determined the contact stress limit to be 2000 MPa (290 ksi), identical to the contact stress limit of all-steel bearings (Ref 13).

The rolling contact fatigue life of hot-pressed silicon nitride (HPSN) balls containing yttria and alumina additives have been found to be greater than conventional ball bearings steel balls (Ref 14).

The continuing research into the use of ceramics in rolling contact bearings for both high-speed and high-temperature applications has produced encouraging successes. Note, however, that these bearings are expensive and must be specially designed by bearing specialists to ensure reliable performance.

Friction and Wear of Carbon-Graphite Materials

Stanley Chinowsky, Pure Carbon Company

Introduction

CARBON-BASED MATERIALS are widely used in friction and wear applications. They are commercially available in hundreds of grades and have a wide range of physical, chemical, and electrical properties. Tribological characteristics can be tailored for numerous applications by the selection of raw materials and manufacturing processes. The combination of carbon-based materials with metallic, polymeric, fiber, inorganic chemical, and other additives can create infinite variety. In the present state of the art, only past experience and testing can determine the suitability of a material for an application.

Carbon, the major chemical constituent of carbon and graphite materials, can vary in terms of its physical structure. It can be amorphous in glassy carbon, turbostratic in carbon black, imperfect hexagonal crystals in coke and coal, near-perfect hexagonal crystals in graphite, or near-perfect tetragonal crystals in diamond. Carbon fibers, in various degrees of chemical purity and crystalline perfection, add to the available choices.

Generally, a material described as carbon suggests an imperfect-to-amorphous crystal structure, processing temperatures up to about 1100 °C (2010 °F), low conductivity, and a relatively hard and abrasive material. Material described as graphite would have a more-perfect crystal structure, and would have been heated to nearly 3000 °C (5430 °F) during manufacture. It would also have higher conductivity and be soft and slippery. Many materials are intermediate in terms of all of the descriptors, and these hybrids are often described as carbon-graphite.

Carbon and graphite materials are manufactured for numerous applications that have little to do with friction and wear. Applications of this type include arc furnace electrodes, battery anodes, electrical discharge machining electrodes, gouging and welding rods, and continuous casting molds. In some of these applications (electrodes and gouging rods), materials are optimized for minimum wear from erosion and oxidation. In other cases (continuous casting), friction plays a role. However, materials used in these applications are not primarily engineered for friction and wear.

Friction and wear applications of carbon and graphite materials can be classified as being either electrical or mechanical, depending on whether electric current is carried by the carbon rubbing component. Materials are tailored for one or the other type of use; it would be very unusual for a material to find application in both areas. Electrical carbons are used for motor brushes, potentiometer contacts, and other applications in which current must be transferred across a sliding interface. Mechanical carbons are used for sliding members that do not carry current, such as bearings, seals, pump vanes, and rotors.

Electrical carbons are frequently low in strength (less than 35 MPa, or 5.1 ksi, in flexural strength), because forces are generally low and are often in compression. Mechanical carbons are subjected to larger forces that can stress the carbon in tension and are therefore usually stronger and stiffer.

Metals are often combined with carbon to make composite materials with increased conductivity and strength. Copper, silver, lead alloys, and antimony are commonly used for both electrical and mechanical applications. The combination can be accomplished by either mixing powders before compaction of the material or infiltrating a porous carbon body with a molten metal.

Organic and inorganic compounds of all kinds can also be combined with carbon to influence various properties. As with metals, such additions can be made during powder mixing or by the infiltration of liquid compounds or solutions. Fluorine compounds and molybdenum disulfide are used to improve friction and wear in low-moisture environments. Phosphorus and boron compounds can improve resistance to oxidation. Oils and waxes can be used to modify friction. Possible additives to carbon are almost limitless, because carbon is inert to most reagents. Usually, additives are combined physically with the carbon base material, with no chemical interaction.

Because carbon and graphite materials are produced by pyrolysis of hydrocarbon binders, they are normally porous. The porosity makes it possible to infiltrate materials, as discussed above, to modify properties, but to also leave the materials permeable to fluids. In applications where permeability must be limited or eliminated, such as seals, the pores are filled with an impermeable material, usually a polymer. Phenolic, polyester, and epoxy resins are all commonly used. Applications, such as air bearings, can also make use of the inherent porosity of carbon and graphite.

The addition of other materials to carbon makes the resultant product more susceptible to environmental deterioration than the base carbon itself. Because almost any additive has a lower temperature capability than the carbon itself, the additive limits the operating temperature. Oxidation is an exception. Similarly, because almost any additive is more reactive chemically than carbon, thermal oxidation excepted, the additive determines resistance to attack by corrosive reagents.

Manufacturing Methods

Conventional carbon manufacturing technology uses particulate fillers with either liquid or thermoplastic binders. A mixing process disperses the fillers in the binder and coats the filler particles in the process. The binder is fluid during the mixing process, either through dissolution (as in some resin systems) or by heating (used with pitch or solvent-free resins). The mix can be extruded directly into long cylinders, or it can be further processed to make powder for molding via several different processes, such as extrusion, uniaxial compression in dies in mechanical or hydraulic presses, or isostatic pressing.

After molding, the green compacts are baked to about 1100 °C (2010 °F) to carbonize the binder. For some materials, the initial baking or carbonizing is followed by higher-temperature heat treatments, such as up to 3000 °C (5430 °F) for some graphites. Baked and heat-treated blanks or billets are machined and treated by various infiltration processes to achieve final composition and properties.

Fiber-reinforced carbon materials (carbon-carbon composites) are made with carbon fiber fillers, rather than particulate fillers. The manufacturing technology for both particulate and fiber-filled carbon is similar to methods used for polymer composites, where processing is complete after the binder is cured. The presence or absence of the carbonization process is what differentiates polymer composites from carbon and graphite materials.

Physical and Mechanical Properties

When compared with metals, particulate carbons are low-density brittle materials. Their values for modulus of elasticity and tensile strength are low, but their compressive strength is higher than tensile strength. Thermal conductivity varies widely with the type of carbon. The limiting temperature for practical use is determined by either oxidation rate or changes in the materials used for impregnation.

Table 1 shows how properties can vary from a pure carbon to a pure graphite composition. Fully graphitic material is much higher in thermal conductivity and oxidation resistance, at the expense of hardness and strength. Table 2 shows how the properties of a carbon-graphite are altered by impregnation with a polymer, a metal, and an inorganic salt. The treatments increase strength and density in particular, As discussed in the section "Friction and Wear" below, they also modify tribological behavior.

Table 1 Properties of typical carbon and graphite materials

Property	Carbon (100%)	Carbon-graphite (70%-30%)	Graphite-carbon (70%-30%)	Graphite (100%)
Apparent density, g/cm^3	1.70	1.72	1.75	1.80
Hardness, scleroscope	100	85	65	40
Compressive strength, MPa (ksi)	300 (43)	208 (30)	145 (21)	55 (8)
Flexural strength, MPa (ksi)	62 (9)	62 (9)	52 (7.5)	28 (4)
Modulus of elasticity, GPa (10^6 psi)	21 (3)	17 (2.4)	14 (2.1)	10 (1.4)
Thermal conductivity, W/m · K (Btu · ft/h · ft^2 · °F)	5 (3)	9 (5)	12 (7)	85 (50)
Temperature limit (air), °C (°F)	315 (600)	315 (600)	315 (600)	455 (850)

Table 2 Impregnation effects on typical carbon-graphite base material

Property	Not impregnated	Phenolic resin impregnated	Silver metal impregnated	Lithium fluoride impregnated
Apparent density, g/cm^3	1.72	1.80	2.40	1.85
Hardness, scleroscope	85	90	95	90
Compressive strength, MPa (ksi)	280 (30)	241 (35)	310 (45)	276 (40)
Flexural strength, MPa (ksi)	62 (9)	76 (11)	93 (13.5)	86 (12.5)
Modulus of elasticity, GPa (10^6 psi)	17 (2.4)	21 (3.1)	27 (3.9)	21 (3)
Thermal conductivity, W/m · K (Btu · ft/h · ft^2 · °F)	9 (5)	9 (5)	14 (8)	9 (5)
Temperature limit (air), °C (°F)	315 (600)	260 (500)	290 (550)	315 (600)

Table 3 shows similar effects for a graphite-base material. Note that this graphite is about twice as strong as the graphite listed in Table 1, illustrating the great dependency of properties on materials and processes used for specific compositions.

Table 3 Impregnation effects on typical graphite-base material

Property	Not impregnated	Phenolic resin impregnated	Silver metal impregnated	Carbon impregnated
Apparent density, g/cm^3	1.82	1.90	2.40	1.88
Hardness, scleroscope	75	80	80	80
Compressive strength, MPa (ksi)	138 (20)	172 (25)	200 (29)	145 (21)
Flexural strength, MPa (ksi)	55 (8)	66 (9.5)	76 (11)	61 (8.8)
Modulus of elasticity, GPa (10^6 psi)	12 (1.8)	14 (2.0)	17 (2.4)	14 (2.1)
Thermal conductivity, W/m · K (Btu · ft/h · ft^2 · °F)	70 (40)	60 (35)	85 (50)	70 (40)
Temperature limit (air), °C (°F)	455 (850)	260 (500)	480 (900)	455 (850)

Fiber-reinforced carbons can be much stronger and stiffer than particulate carbons, but properties may be strongly anisotropic. The properties of particulate carbons are usually relatively isotropic. Coarse-grained extruded carbon can show marked anisotropy, but such materials are not usually applied to tribological areas. The thermal expansion of particulate mechanical carbons is lower than it is for metals and polymers, and is comparable to that of ceramics.

Friction and Wear

The tribological characterization of carbon and graphite materials is commonly done under dry or boundary lubrication conditions. Performance is influenced by environment, mating material, surface finish, load, and speed. Friction and wear must be characterized for a mating pair, that is, for a carbon-mating material combination, rather than the carbon itself.

Figure 1 illustrates the great effect that mating material has on the apparent behavior of a specific carbon in dry wear tests. The mating material effects not only the magnitude of the carbon wear, but also its temperature dependence. Note that wear is expressed in a dimensionless unit obtained by dividing the wear depth by the distance rubbed in the test.

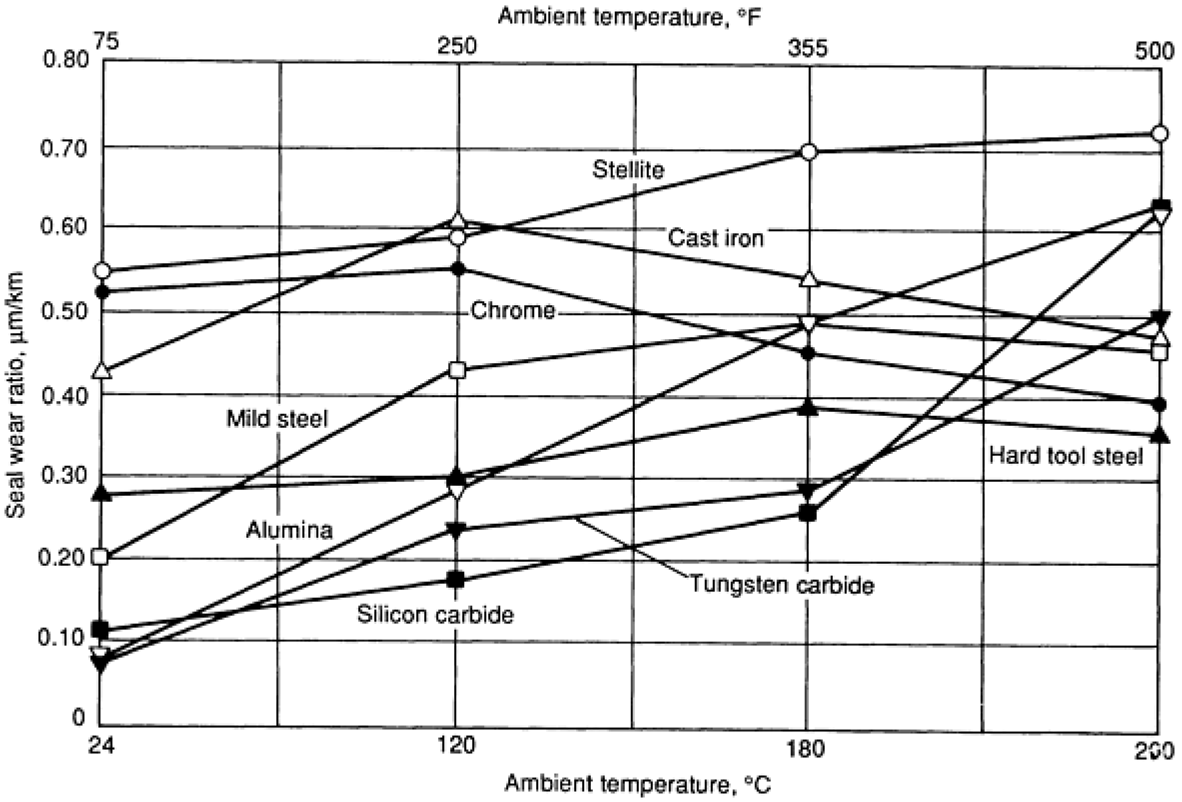

Fig. 1 Wear of a resin-impregnated carbon-graphite against various mating materials. Load, 138 kPa (20 psi); speed, 135 m/min (442 ft/min)

Wear of the mating material is dependent on the carbon rubbing against it. An abrasive, high-ash carbon material can even cause high wear to occur in very hard mating materials, such as tungsten carbide, as shown in Fig. 2.

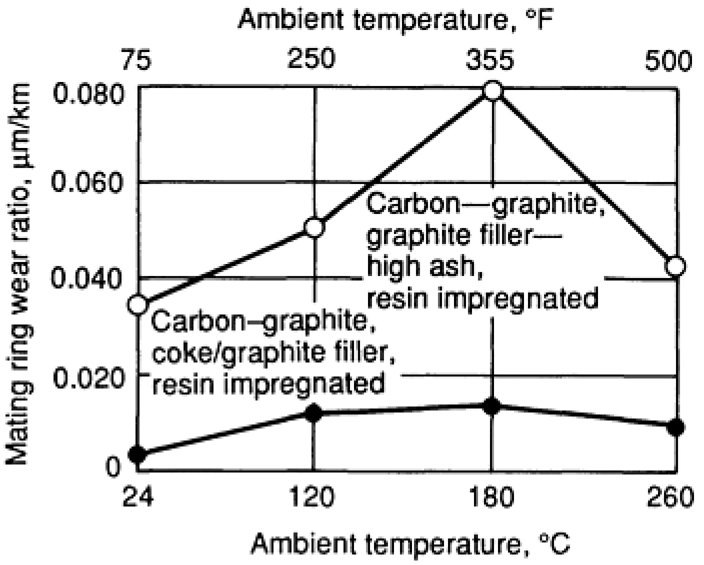

Fig. 2 Mating ring wear with different carbon-graphite materials. Mating material, tungsten carbide; load, 138 kPa (20 psi); speed, 135 m/min (442 ft/min)

Different types of carbon exhibit marked differences in friction and wear for the same conditions. Behavior is often not what might be predicted from physical properties or generic material descriptions. Figure 3 shows that the harder carbon-graphite materials wear more than the relatively soft electrographite material.

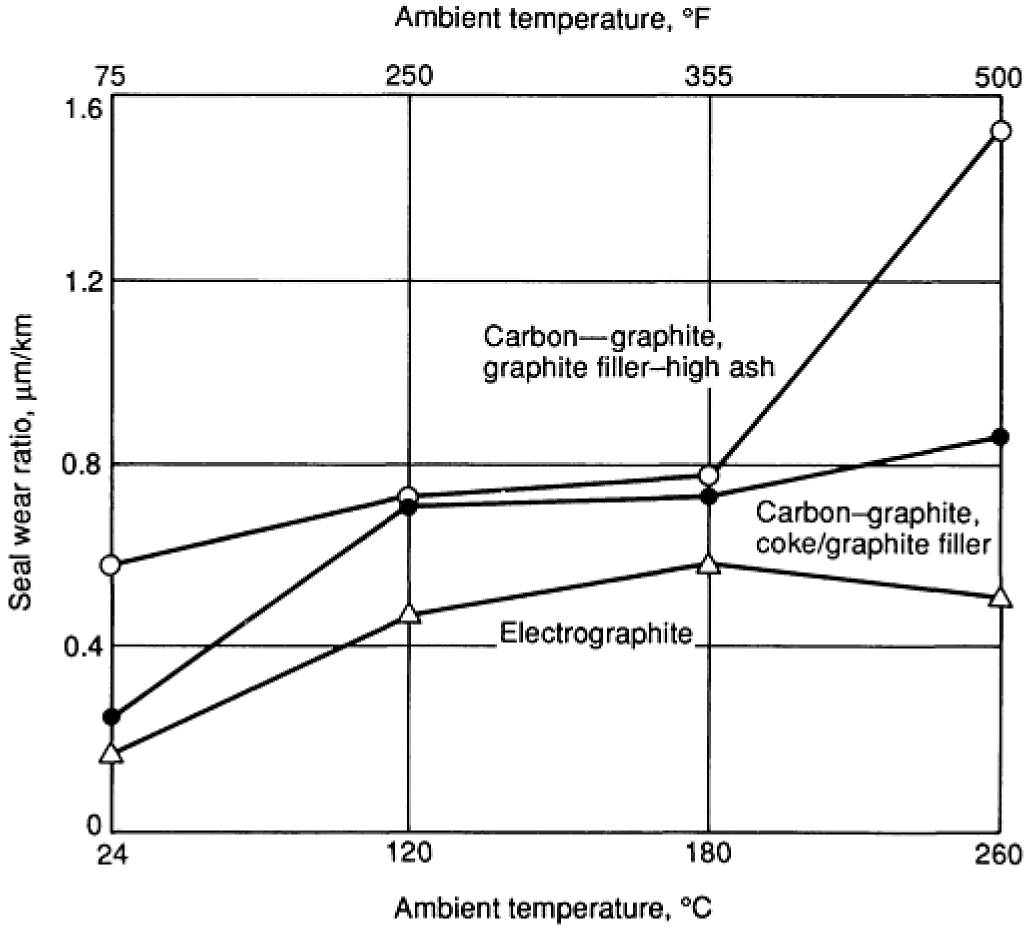

Fig. 3 Wear of different types of carbon. Mating material, SAE 1020 steel; load, 138 kPa (20 psi); speed, 135 m/min (442 ft/min)

Such results apply to the specific grades tested only. It does not follow what all carbon-graphites will wear more than all electrographites under all conditions. Dry rubbing behavior of carbon and graphite materials cannot be predicted in any general or theoretical way. Recommendations can be made for specific cases, based on laboratory tests and field experience. Such recommendations can be made by manufacturers of carbon materials, using their databases from past applications. However, performance should always be verified by the user before final acceptance of the rubbing material system.

Unanticipated results are often found for friction, as well as wear. Generically, one might expect lower friction from a "slippery" electrographite than from a more-abrasive carbongraphite. However, Fig. 4 shows a case where the reverse is true.

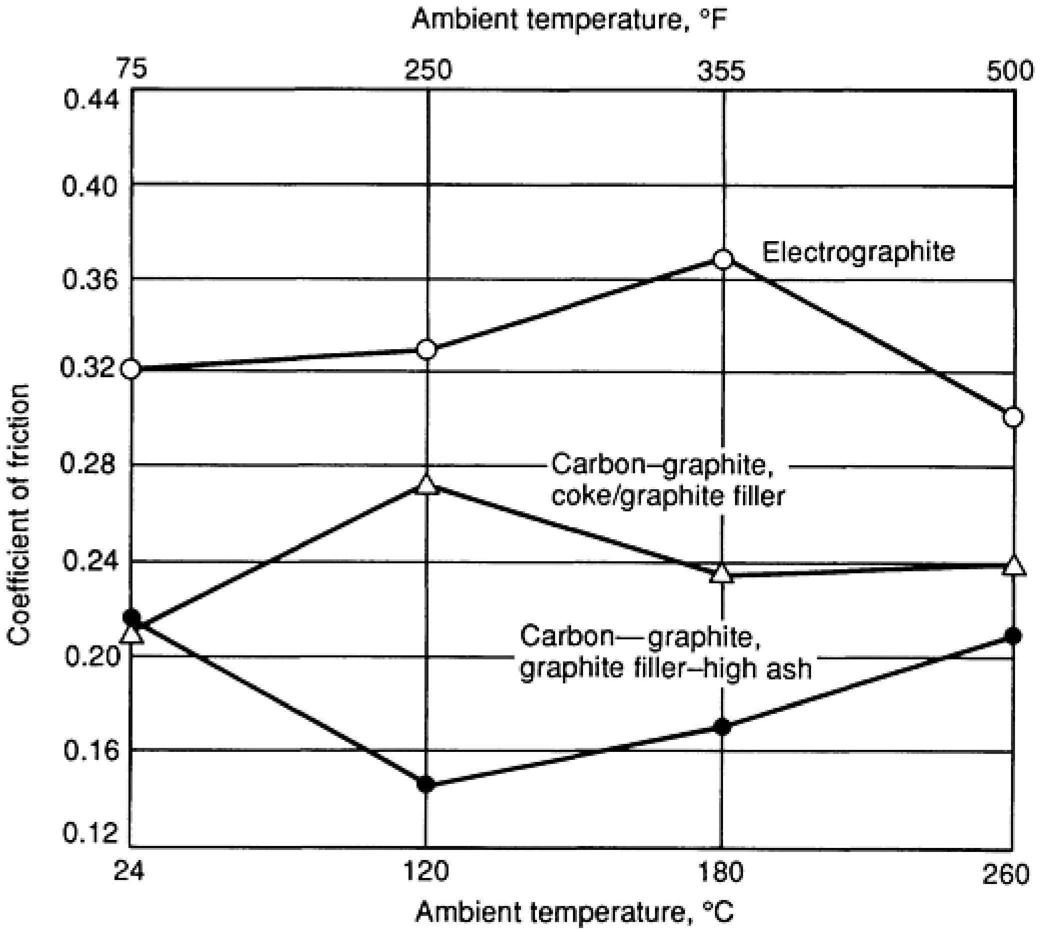

Fig. 4 Friction of different types of carbon. Mating materials, SAE 1020 steel; load, 138 kPa (20 psi); speed, 135 m/min (442 ft/min)

This figure illustrates a segment of carbon and graphite tribology that is sometimes called "film control." The rubbing interface often consists of a thin layer of carbon transferred to the mating ring in the early stages of rubbing. If the transfer film is heavy, as is often the case with graphitic materials, high friction can result. Harden carbons usually deposit a thinner transfer film, generally leading to lower friction.

Filming and other tribological results are influenced by impregnation of basic carbon materials. Figure 5 shows the effects of different types of impregnants on an electrographite.

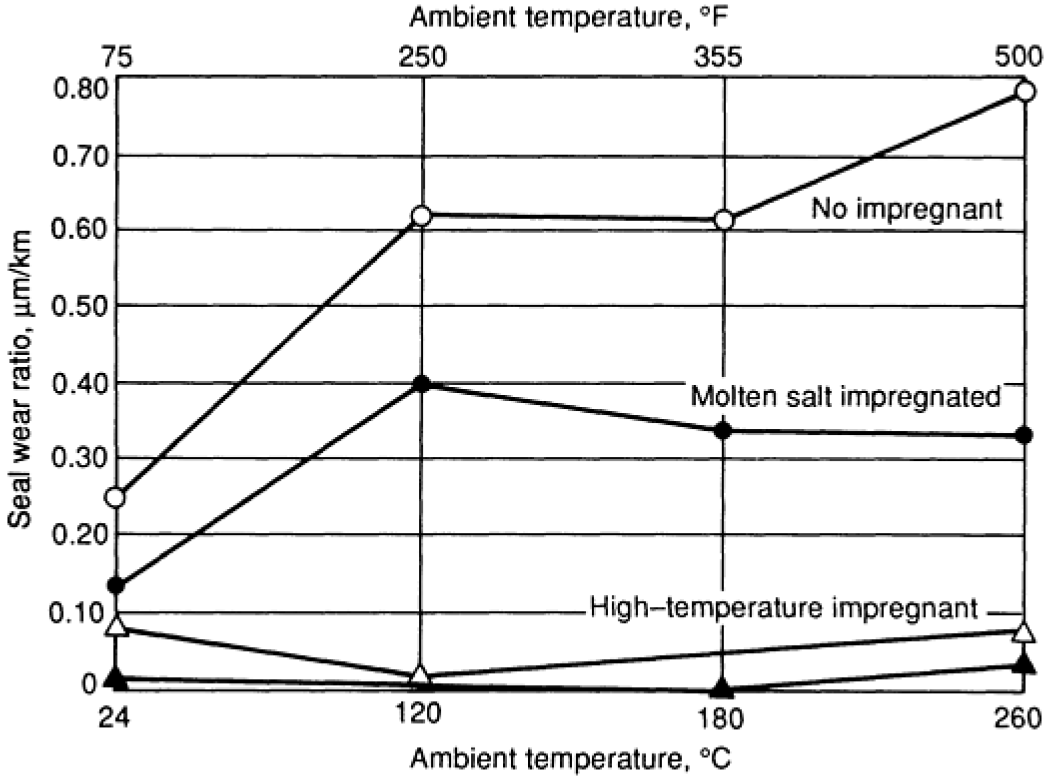

Fig. 5 Wear of an electrographite and related grades. Mating material, chromeplated steel; load, 138 kPa (20 psi); rubbing speed, 135 m/min (442 ft/min)

A similar caveat applies to generalization of the data shown in Fig. 5. The results illustrated were obtained for a specific electrographite with specific impregnants. The same impregnants applied to other electrographites, or to other carbon materials, could produce very different results.

Impregnants influence friction, as well as wear. In one case shown in Fig. 6, a high-temperature impregnant can increase friction at room temperature, but decrease it greatly at higher temperatures.

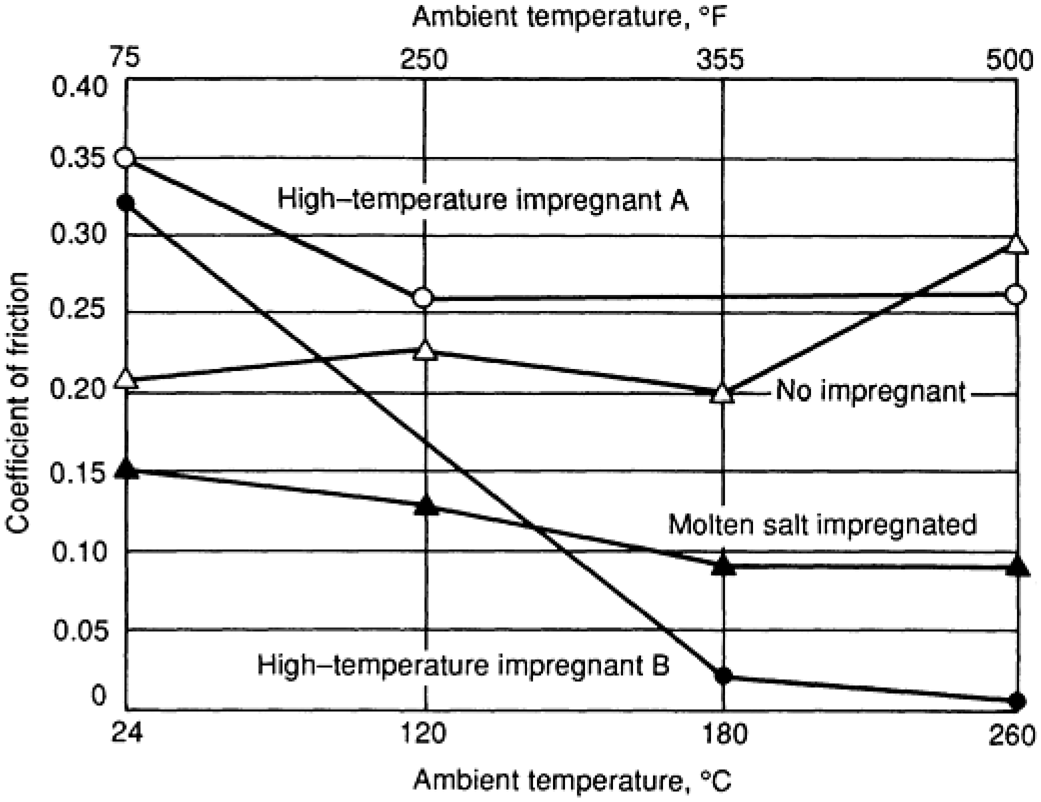

Fig. 6 Friction of electrographite and related grades; same material and conditions as Fig. 5

In boundary and hydrodynamically lubricated applications, wear and friction can be much lower than in the dry rubbing examples presented. Lubrication in these applications in often provided by a film of liquid, such as water, that does not possess lubricating qualities, but does serve to separate parts that are moving relative to each other. The coefficient of friction in seals running with boundary lubrication is typically less than 0.1. In bearings that are hydrodynamically lubricated, the coefficient of friction is less than 0.01, once the hydrodynamic film is formed.

In many applications where the steady state is a lubricated one, the transient start-up and shutdown conditions involve dry rubbing. Carbon and graphite materials are often able to survive the dry running intervals that dictate the selection of carbon for the application. Except for other types of self-lubricating materials, only carbon can be applied without the addition of a lubricating system to protect against failure from dry rubbing.

Although the dry rubbing data illustrates the effects on friction and wear of mating material and temperature, other operating variables are of equal importance. Rubbing speed must be considered, and its effect is not obvious. Some carbon materials will perform better at slow speeds, whereas other materials may run with much lower wear rates at high speeds. For dry rubbing, atmospheric composition is critical, particularly with respect to moisture content. Carbon materials formulated specifically for operation in dry conditions are available. The use of a material that is not suitable for a dry atmosphere may cause the carbon to literally disappear in a cloud of dust.

Under conditions such as cyclic temperature and pressure, some fluids will interact with carbon to cause surface disruptions, called blisters Some grades of carbon resist this failure mechanism better than others. Prior history, laboratory testing, and field verification should all be used in material selection.

Component Design

Performance in specific environments can be strongly influenced by component design. Grooves and indentations of various kinds can be used to balance fluid pressure and reduce effective contact pressure. Grooves can be used in dry applications to aid in wear debris removal, thereby reducing wear.

Mechanical limitations imposed by the strength and modulus of carbon can be dealt with by retaining the carbon in a metal component. Assembly can be accomplished with adhesives, mechanical fasteners, or an interference fit obtained by heating the metal component before assembly. The low modulus of carbon makes the interference fit relatively easy to accomplish, but the resulting distortion of the carbon makes it necessary to finish-machine the carbon after assembly. Because the coefficient of expansion of the metal retainer is always significantly higher than that of the carbon, the temperature capability of the assembly is limited by the amount of interference.

Friction and Wear of Thermoplastic Composites*

Introduction

INJECTION-MOLDABLE THERMOPLASTIC COMPOSITES are increasingly displacing metals in many gear and bearing applications. The ease and economics of manufacturing complex parts by injection molding are well recognized. The ability to absorb shock and vibration, and to operate with less power and noise--with little or no maintenance--are additional advantages gained with thermoplastic composites. Further improvements in mechanical and tribological properties can be attained through the incorporation of glass or carbon fiber reinforcement and polytetrafluoroethylene (PTFE) or other lubricants. These fillers, reinforcements, and lubricants, when compounded with the appropriate base resin, yield an almost limitless array of compounds that provide increasing load-carrying capacity, reduced coefficients of friction, improved wear life, higher mechanical strengths, improved thermal properties, greater fatigue endurance and creep resistance, and excellent dimensional stability and reproducibility.

A large amount of tribological data has been gathered for thermoplastic composites at room temperature. However, continuing tribological characterization of these composites at elevated temperature is required to assist design engineers in expanding their use to more demanding applications. This article focuses on the results of studies performed by the authors on the elevated-temperature friction and wear properties of thermoplastic composites. These results also provide an indication of the overall tribological behavior of polymeric materials.

Previous studies have demonstrated that wear rates and coefficients of friction in plastics versus steel increase with the temperature of the surrounding environment (Ref 1). New opportunities in the transportation industry indicate that increased thermal capabilities for thermoplastic composites are required. As new resins are developed to meet these demands, internally lubricated composites must be developed with corresponding thermal stability and increased resistance to wear at elevated temperatures. To this end, internal lubricant additive with superior thermal stability must be developed and characterized.

The inherent corrosion resistance of plastics is well recognized. This property has become increasingly more important in the chemical process industry and the materials transport industry. Increasing demands are being placed on the structural properties of thermoplastic composites, particularly at elevated temperatures. A large amount of data exist for the structural properties of high-temperature thermoplastic composites. Designers require similar data for the tribological behavior of these composites.

Note

* Adapted from "The Effects of Lubricants and Reinforcements on the Tribological Properties of Thermoplastic Composites at Elevated Temperatures," by Mark P. Wolverton, Kathleen Talley, and John E. Theberge (in *Tribology of Composite Materials,* ASM International, 1990)

Sliding Wear in Thermoplastic Composites

The frictional properties of thermoplastic composites vary in a unique way from metals. When contrasted with metals, even highly reinforced resins have low modulus values and their asperities will more greatly deform under load. The friction between thermoplastic composite and metal surfaces is characterized by adhesion and deformation, resulting in frictional forces that are not proportional to load (that is, the coefficient of friction decreases as load increases) but are proportional to speed (Ref 2).

Wear rate is often defined as the volumetric loss of material over a unit of time. Several mechanisms operate simultaneously to remove material from the wear interface. The primary mechanism is adhesive wear, which is characterized by fine particles of polymer being removed from the surface. The presence of this powder is a good indication that the rubbing surfaces are wearing properly. The presence of melted polymer or large gouges or grooves at the interface is normally an indication that the materials are not wearing by adhesion but rather by abrasion, or an indication that the pressure velocity limit of the material has been exceeded.

The wear of an unlubricated surface in sliding is proportional to the load multiplied by the distance traveled (Ref 3):

$$W \approx FD \qquad \textbf{(Eq 1)}$$

$$W \approx FVT \qquad \textbf{(Eq 2)}$$

The parameters in Eq 1 and 2 are defined in Table 1. Introducing a factor of proportionality (the wear factor), *K*, Eq 2 becomes

$$W = KFVT \qquad \textbf{(Eq 3)}$$

Solving for *K* yields:

$$K = \frac{W}{FVT} \qquad \textbf{(Eq 4)}$$

Table 1 Parameters that affect sliding wear of unlubricated surfaces

Parameter	Definition	Units	
		Metric	**English**
W	Wear volume	mm^3	$in.^3$
F	Force	N	lbf
V	Velocity	m/s	ft/min
T	Elapsed time	s	h

The wear factor for a thermoplastic composite is generated by the thrust washer test procedure (ASTM D 3702). The static and dynamic coefficients of friction are also generated using this test. Once a wear factor, *K*, has been established, it can be used to calculate wear rates of bearings, gears, and so on. However, because wear rate is affected by material type, finish, and hardness, as well as by environmental temperature and part design, large errors may result as end-use variables begin to differ from those selected for the test. As a measure of the performance of one composite relative to another at the same operating conditions, the *K* factors have proven to be highly reliable. The units for the *K* factor in this paper are in the English units most familiar to the design engineers who use these data. A conversion to SI units yields 1×10^{-10} $in.^3 \cdot min/ft \cdot lbf \cdot h = 2.014 \times 10^3$ $mm^3/N \cdot m$.

Wear Tests

Wear Factor. Wear tests are conducted with a thrust washer test apparatus, as described in ASTM D 3702. The sample thrust washer is mounted in an antifriction bearing equipped with a torque arm. The raised portion of the thrust washer bears against a dry, cold rolled, carbon steel wear ring with 0.30 to 0.40 μm (12 to 16 μin.) finish and 18 to 22 HRC

hardness. Each evaluation is conducted with a new wear ring that has been cleaned and weighed on an analytical balance. Weight loss and frictional torque are continuously monitored. Figure 1 is a schematic representation of this test.

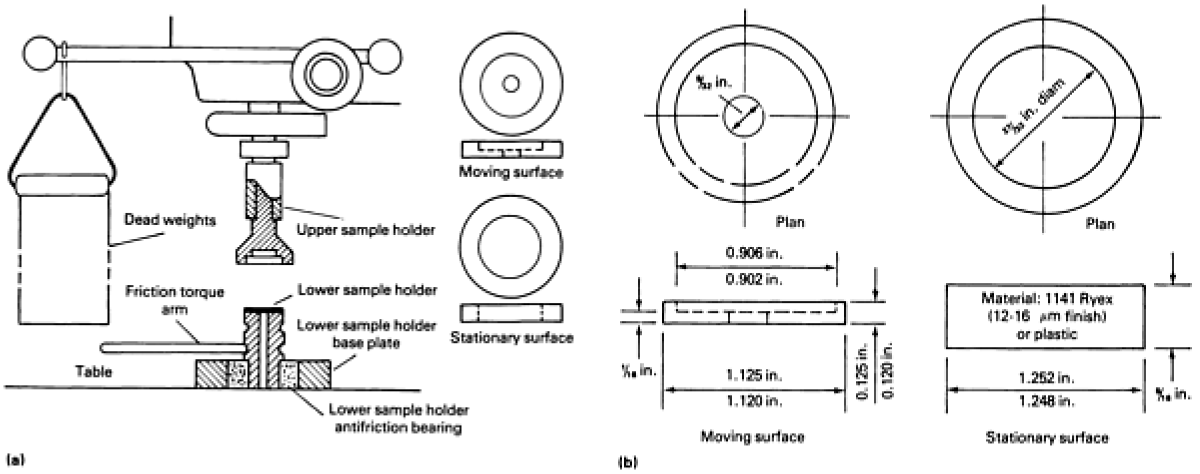

Fig. 1 ASTM D 3702 test used to determine wear rates of self-lubricated materials. (a) Schematic showing thrust washer test apparatus. (b) Schematic showing dimensions of moving test specimen and stationary washer

The test duration depends upon the period required to achieve 360° contact between the raise portion of the thrust washer and the wear ring. The average wear factor and duration of this break-in period are recorded. The wear factors reported for each compound are based on the equilibrium wear rate independent of break-in-wear.

Volume wear is calculated as follows:

$$W = \frac{m}{\rho} \quad \text{(Eq 5)}$$

where W is wear volume in cm^3; m is the weight loss in milligrams; and ρ is density in g/cm^3. This volume is substituted into Eq 3 for calculation of the wear factor, *K.*

Coefficient of friction data were obtained with the thrust washer test apparatus. The test specimen is run in against the standard wear ring until 360° contact between the raise portion of the thrust washer and wear ring is achieved. Temperature of the test specimen is then allowed to stabilize at the test conditions (force of 280 kPa, or 40 psi; velocity of 0.25 m/s, or 50 ft/min). After thermal equilibrium occurs, the dynamic frictional torque generated is measured with the torque arm mounted on the antifriction bearing. The average of a minimum of five readings is taken.

In this study, the thrust washer testers were modified with thermal chambers that allowed independent control of the test temperature. Test specimens were allowed to come to equilibrium with the chamber temperature before the application of load and motion.

Material Selection

Identification of and formulations for the composites that were studied are found in Table 2. This material identification will be used throughout this discussion. The results of the wear and friction testing are presented in Tables 3, 4, 5, 6. Mechanical properties for the composites are presented in Table 7. The relative thermal stability of selected lubricant additives are shown in the thermogravimetric analysis (TGA) curves of Fig. 2.

Table 2 Composition of injection-moldable thermoplastic composites

Material	Base resin[(a)]	Reinforcement		Lubricant	
		Type	**%**	**Type**	**%**
LCL-4023	PEEK 150G	Carbon fiber	15	PTFE	10
LCL-4033 (150)	PEEK 150G	Carbon fiber	15	PTFE	15

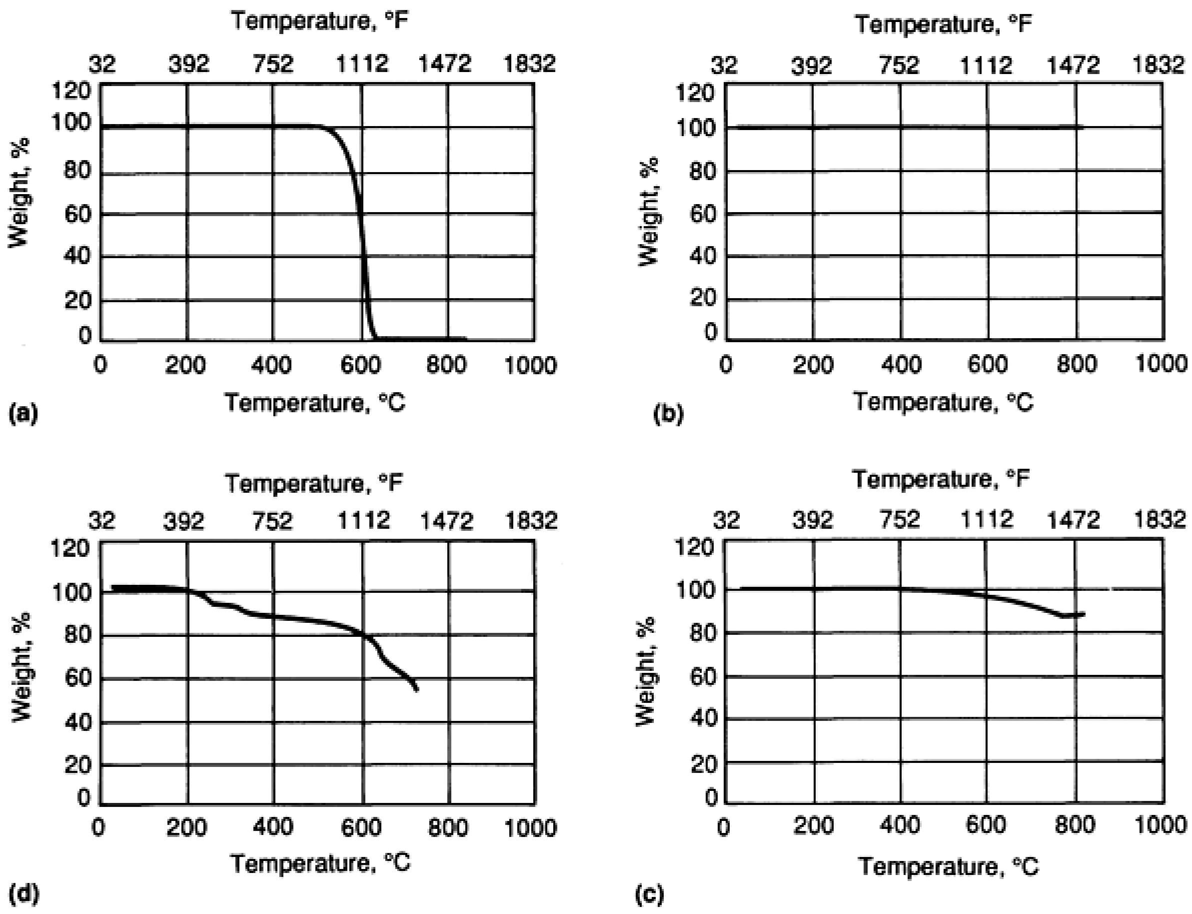

Fig. 2 Thermogravimetric analyses of lubricant additives. (a) PTFE. (b) Calcium fluoride. (c) Intercalated graphite. (d) $SbSbS_4$

Wear and friction data for polyether etherketone (PEEK) resin and composites are presented in Table 3. While all additives in this study reduced the wear factor, it is important to note that the addition of fibrous reinforcement (for example, carbon fibers) is required to develop minimum wear at elevated temperatures. Wear factor and both coefficients of friction increase with increasing temperature in the PEEK composites evaluated.

Effect of Lubricant on Wear Factor. As expected, compounds using high-molecular-weight PEEK resins (for example, PEEK 450G) had lower wear factors than identical compounds based on lower molecular weight resins (for example, PEEK 150G) at room temperature. However, at 260 °C (500 °F) the reverse is true; that is, PEEK 150G materials has lower wear factors (Fig. 3). This is due to the improved bonding of the fiber at the polymer interface.

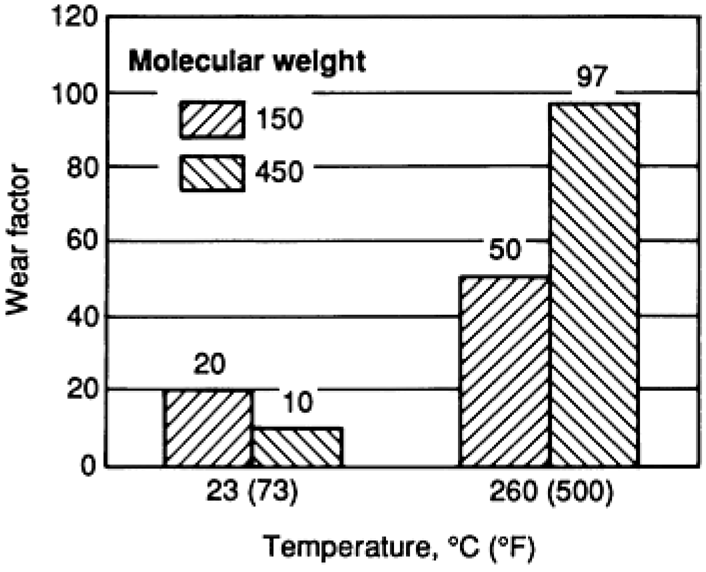

Fig. 3 Effect of molecular weight on the wear factors of carbon fiber/PTFE/PEEK composites

PTFE and graphite powder are often used as internal lubricants for thermoplastic composites. They have been found to be effective lubricants in PEEK. At 23 °C (73 °F), graphite-powder-lubricated carbon-fiber-reinforced PEEK will demonstrate wear and frictional behavior similar to that of the analogous PTFE-lubricated composite. However, at 260 °C (500 °F), the graphite-lubricated composite demonstrates 40% more wear than the PTFE-lubricated composite (Fig. 4).

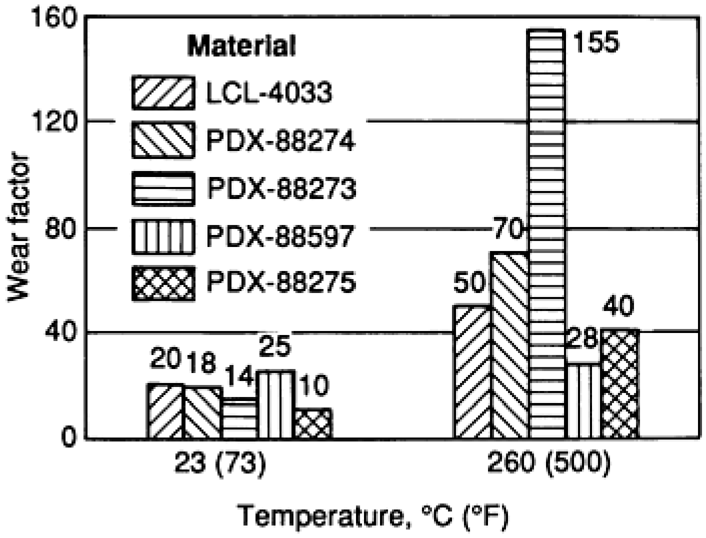

Fig. 4 Effect of lubricant on the wear factors of carbon fiber/PEEK composites

Graphite powder was evaluated in combination with PTFE lubricant in carbon-fiber-reinforced PEEK (PEEK PDX-88275). This lubricant package demonstrated lower wear factors than either lubricant individually at 23 °C (73 °F) and 260 °C (500 °F) (Fig. 4).

Calcium fluoride demonstrated very good lubricating behavior in carbon-fiber-reinforced PEEK at room temperature. However, calcium fluoride is not an effective lubricant at 260 °C 500 °F) (Fig. 4).

Intercalated graphite demonstrated low wear factors when used as an internal lubricant in carbon-fiber-reinforced PEEK at all temperatures. The wear factor for this composite (PDX-88597 at 260 °C (500 °F) was identical to the wear factor at room temperature. At 260 °C (500 °F), the wear factor for the composite was one-fourth that of the analogous PTFE-lubricated composite (LCL-4033) (Fig. 4).

While $SbSbS_4$ is a very effective lubricant in carbon-fiber-reinforced PEEK at room temperature, it loses this effectiveness at 260 °C (500 °F) when compared to the analogous PTFE-lubricated composite (PEEK PDX-88598) (Fig. 5).

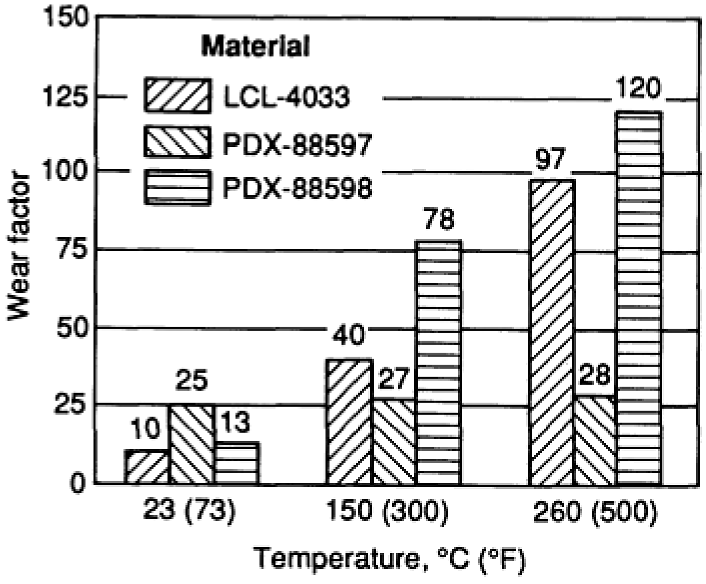

Fig. 5 Effect of lubricant on the wear factors of carbon fiber/PEEK composites

The wear factors of PEEK composites are affected by the load, *P,* and speed components, *V,* independent of total *PV.* All composites demonstrated lower wear factors at low pressures (35 kPa, or 5 psi) and high speeds (2.0 m/s, or 400 ft/min) than at high pressures (280 kPa, or 40 psi) and intermediate speeds (0.25 m/s, or 50 ft/min). This was demonstrated at all temperatures (Fig. 6).

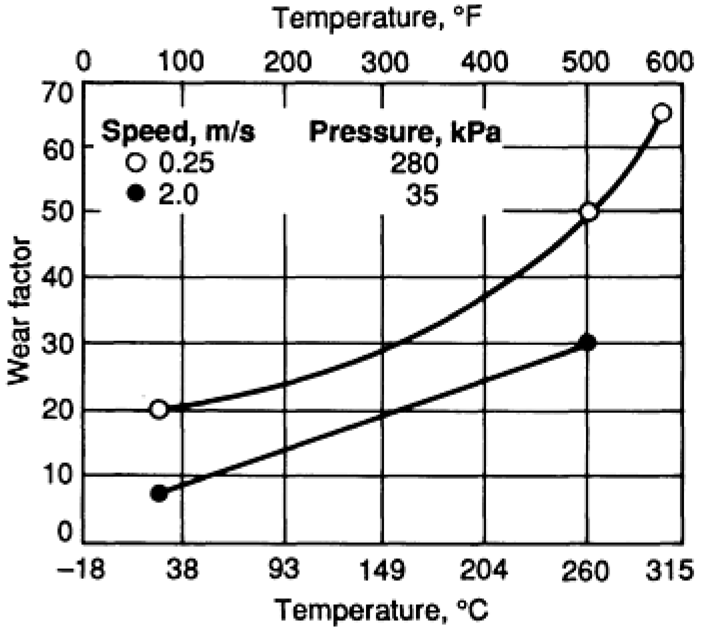

Fig. 6 Plot of wear factor versus test temperature as a function of speed and load for LCL-4033 composite

Carbon-fiber-reinforced PEEK, polyetherketone (PEK), and high-temperature-crystalline (HTX) composites demonstrated similar wear factors at room temperature. The wear factor of carbon-fiber-reinforced PEEK increased threefold when tested at 260 °C (500 °F). (The wear factor of carbon-fiber-reinforced PEEK at 260 °C, or 500 °F, is less than the wear factor of unfilled nylon 6/6 at room temperature.) The wear rates for carbon-fiber-reinforced PEK and HTX were almost the same at 260 °C (500 °F) as at room temperature (Fig. 7).

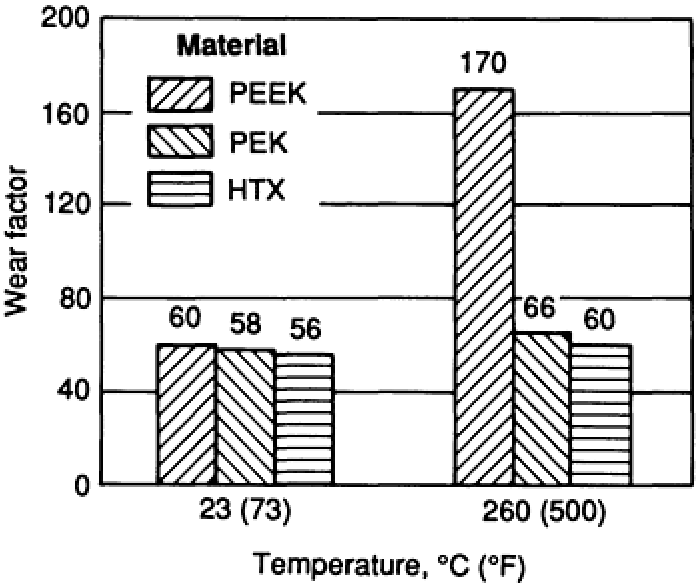

Fig. 7 Effect of temperature on the wear factors of 30% carbon-fiber-reinforced PEEK, PEK, and HTX composites

Polyphenylene sulfide (PPS) is similar to PEEK composites. Lubricomp O-BG demonstrated lower wear factors at 35 kPa (5 psi) and 2.0 m/s (400 ft/min) than at 280 kPa (40 psi) and 0.25 m/s (50 ft/min). As in previous studies for PPS compounds (Ref 1), Lubricomp O-BG displays a maximum service temperature of 205 °C (400 °F) as a bearing material (Fig. 8).

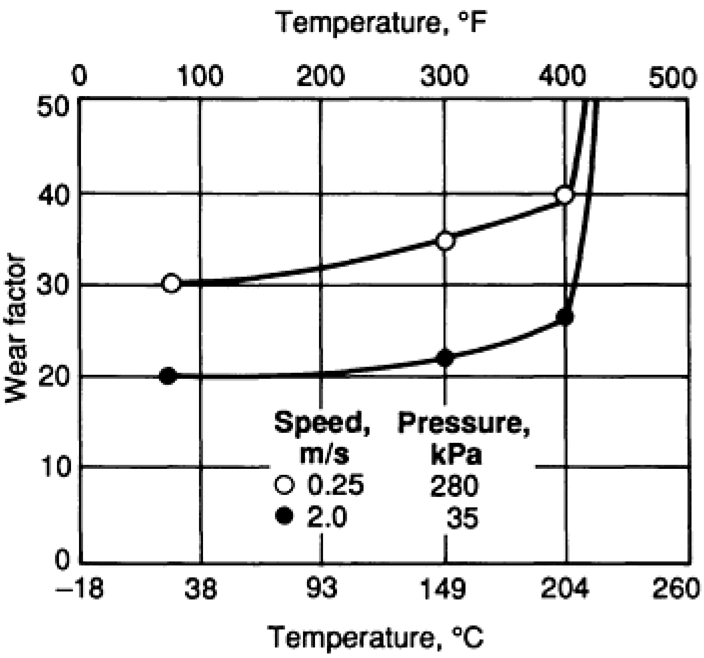

Fig. 8 Plot of wear factor versus test temperature as a function of speed and load for Lubricomp O-BG composite

The wear performance of two different liquid crystal polymers (LCP) was determined in the following study, PTFE reduces the wear factor to a greater extent than graphite at both 23 °C (73 °F) and 150 °C (300 °F). The experimental self-reinforcing polymer (SRP), when lubricated with PTFE, demonstrates significantly lower wear factors and coefficients of friction at room temperature than the liquid crystal polymer Xydar. At 150 °C (300 °F) the SRP/PTFE also demonstrates lower wear and slightly higher coefficients of friction than the LCP/PTFE.

Effect of Lubricants on Friction. There is a distinct trend for compounds based on high-molecular-weight PEEK resins to demonstrate lower static and dynamic coefficients of friction at both room temperature and at 260 °C (500 °F) than for those based on low-molecular-weight PEEK. The greatest difference is found in the static coefficient of friction at 260 °C (500 °F) for the 15% PTFE-lubricated, 15% carbon-fiber-reinforced PEEK composites (Fig. 9).

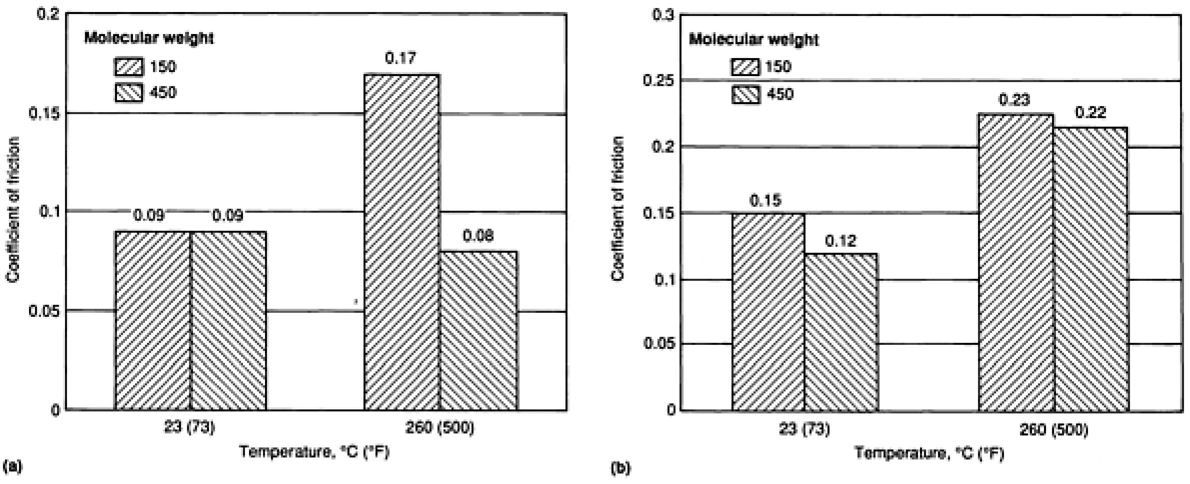

Fig. 9 Effect of molecular weight and test temperature on the coefficients of friction of carbon fiber/PTFE/PEEK composites. (a) Static coefficient of friction. (b) Dynamic coefficient of friction

There are no clear-cut trends for the effects of lubricants on the coefficients of friction. PTFE lubricants demonstrate the lowest static coefficients of friction at all temperatures when compared to metallic lubricants (intercalated graphite, $SbSbS_4$ and CaF_2). However, graphite powder can offer a lower static coefficient of friction than PTFE (Fig. 10 and 11).

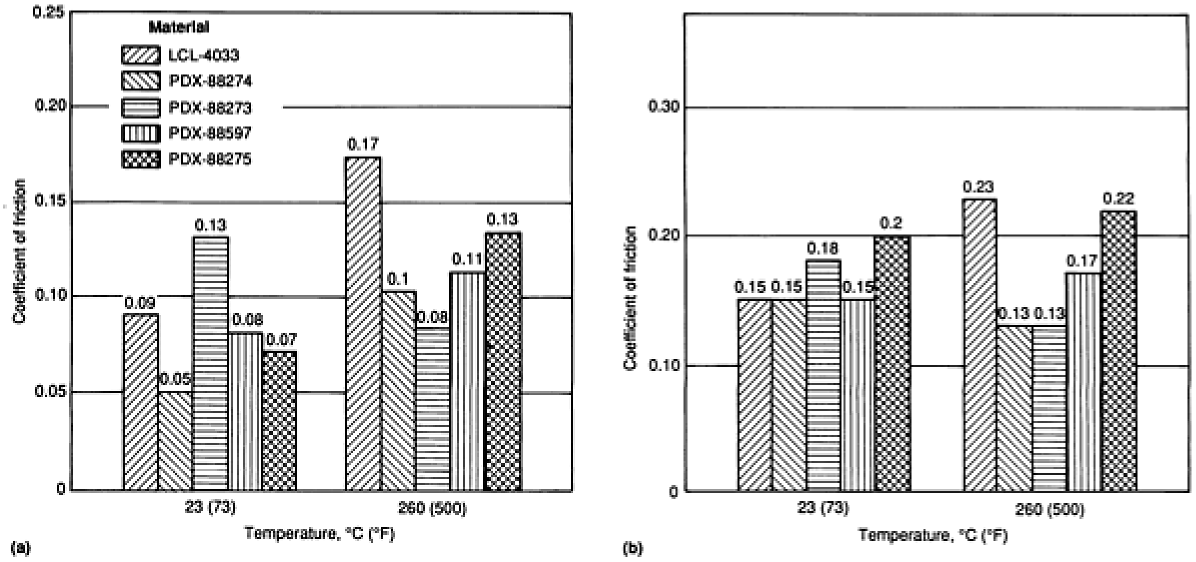

Fig. 10 Effect of lubricant and test temperature on the coefficients of friction of carbon fiber/PEEK composites. (a) Static coefficient of friction. (b) Dynamic coefficient of friction

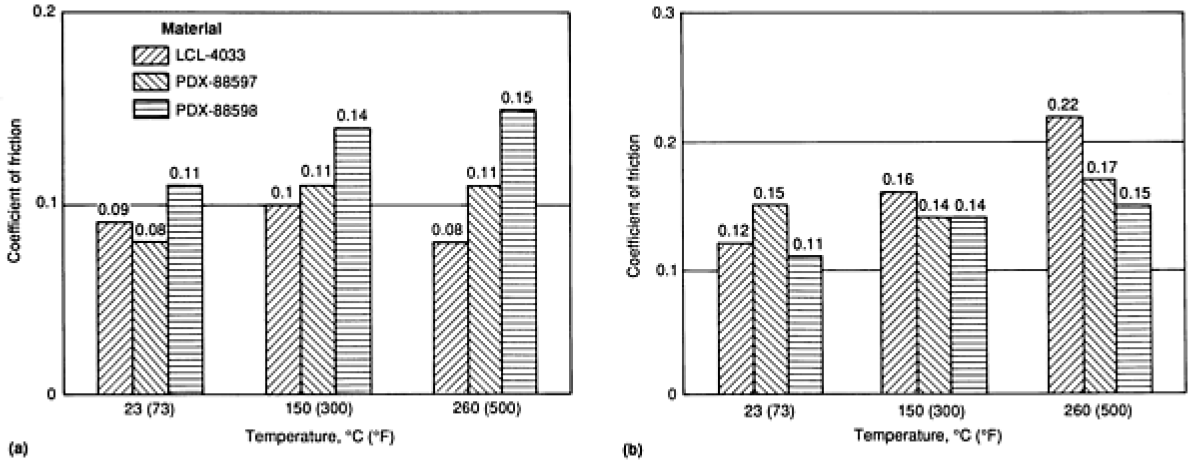

Fig. 11 Effect of lubricant and test temperature on the coefficients of friction of carbon fiber/PEEK composites. (a) Static coefficient of friction. (b) Dynamic coefficient of friction

Coefficients of friction are expected to decrease with increasing thermal stability of the resin (for example, melt point, T_g, or continuous-use temperature). This trend is *not* well demonstrated by 30% carbon-fiber-reinforced PEEK, PEK, or HTX (Fig. 12).

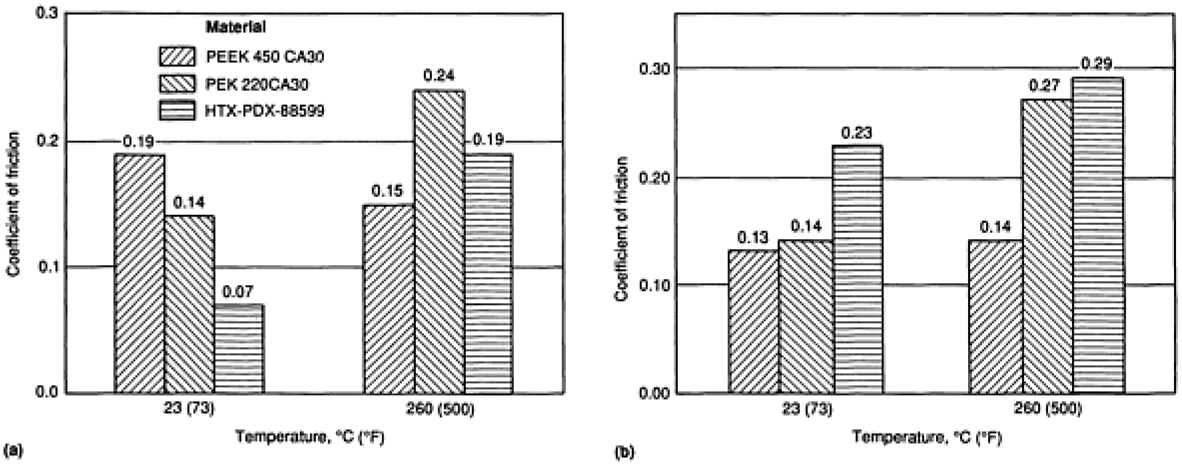

Fig. 12 Effect of test temperature on the coefficients of friction of 30% carbon-fiber-reinforced PEEK, PEK, and HTX composites. (a) Static coefficient of friction. (b) Dynamic coefficient of friction

The coefficient of friction increased for the PTFE-lubricated, carbon-fiber-reinforced PEEK composite with increasing temperature (Fig. 13).

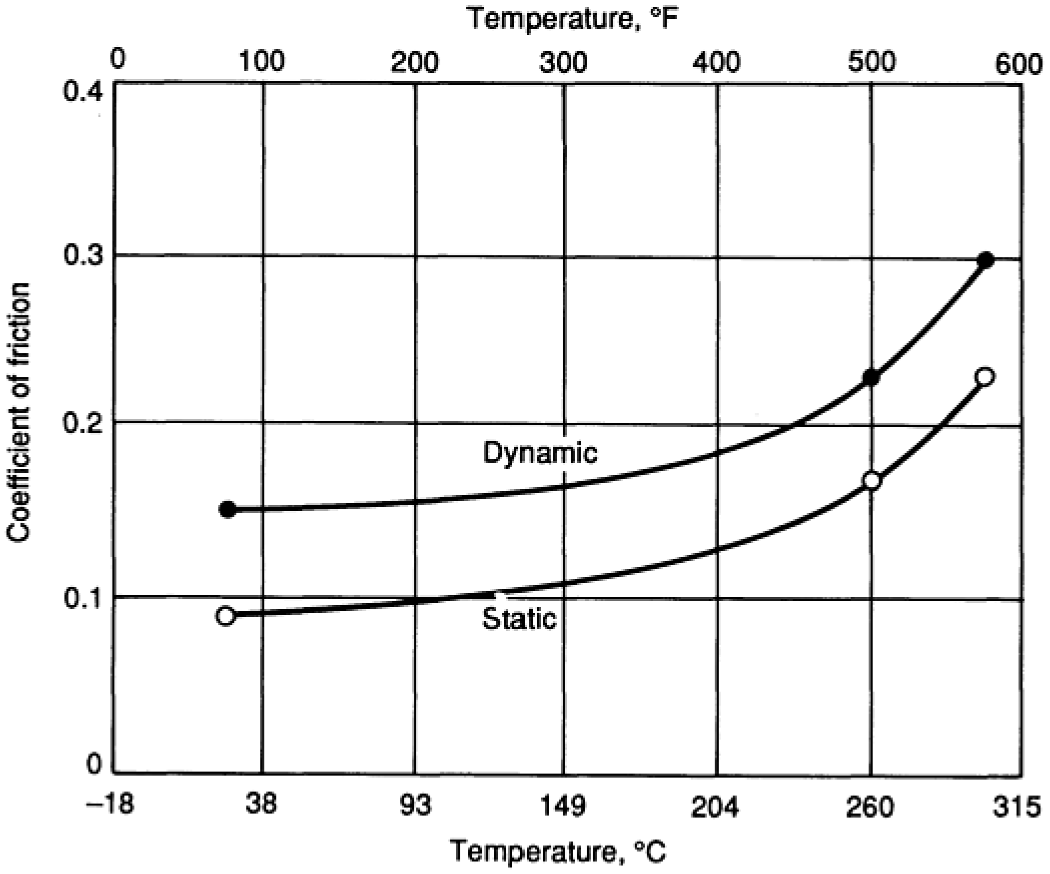

Fig. 13 Plot of coefficient of friction versus test temperature for LCL-4033

The reinforced, lubricated PPS composite demonstrates a clear trend for the dynamic coefficient of friction to increase with temperature. The static coefficient of friction reaches a maximum at approximately 150 °C (300 °F) and then rapidly diminishes with further increases in temperature (Fig. 14).

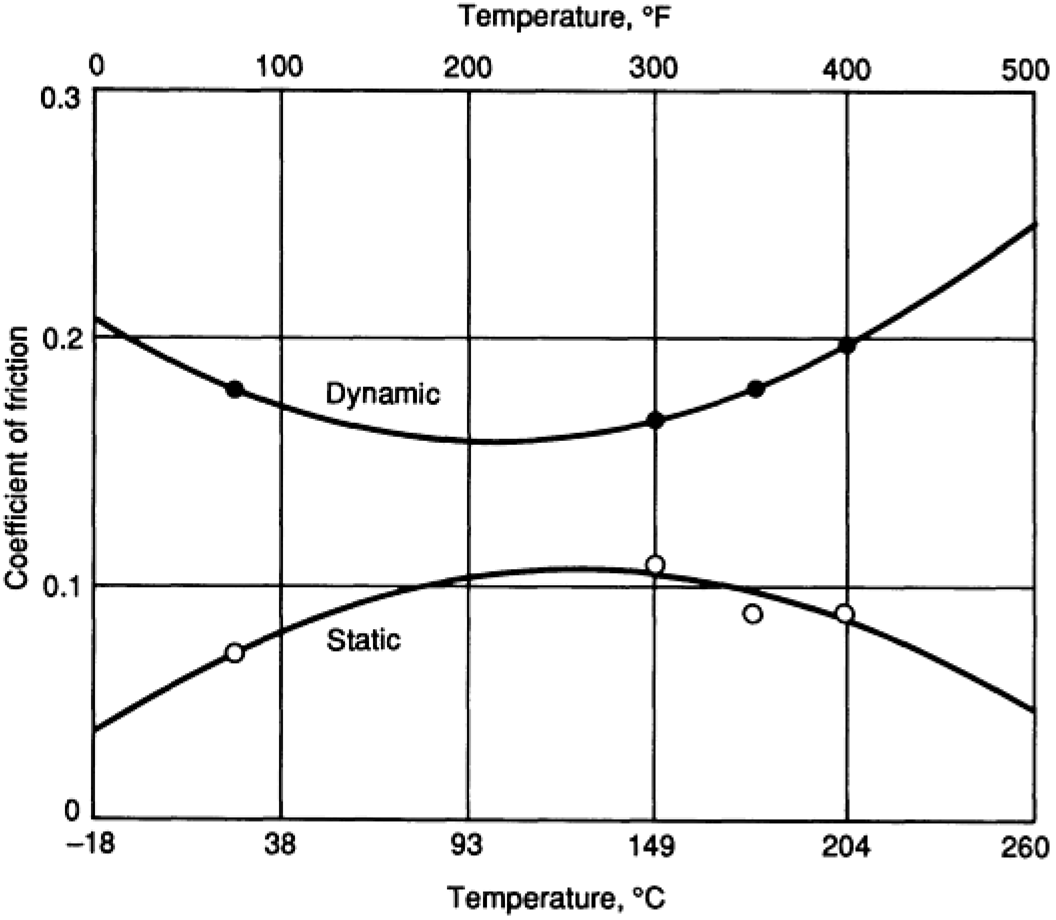

Fig. 14 Plot of coefficient of friction versus test temperature for Lubricomp O-BG

Conclusions. The results of the tests conducted on the composites listed in Table 2 can be summarized as follows:

- PEEK composites formulated with lower molecular weight resin demonstrated lower wear factors than analogs using higher molecular weight resin at elevated temperatures. This is probably due to superior wet-out of the resin and fiber in the low-molecular-weight composites
- Intercalated graphite is a very effective (and expensive) high-temperature lubricant for carbon-fiber-reinforced high-molecular-weight PEEK
- For service to 205 °C (400 °F), Lubricomp O-BG (PPS) and LCL-4033 (PEEK) composites are the materials of choice for wear and friction applications
- For service at 260 °C (500 °F), lubricated PEEK composites are the materials of choice for wear and friction applications
- For service at temperatures in excess of 260 °C (500 °F), composites based on PEK and HTX will be required for wear and friction applications

Thermal Spray Coatings

Burton A. Kushner and Edward R. Novinski, Perkin-Elmer Corporation, Metco Division

Introduction

THE THERMAL SPRAY COATING PROCESS is by far the most versatile modern surfacing method with regard to economics, range of materials, and scope of applications. The thermal spray process permits rapid application of high-performance materials in thicknesses from a few mils to more than 25 mm (1 in.) on parts of a variety of sizes and geometries. Thermal spraying requires minimal base-metal preparation, can be applied in the field, and is a low-temperature (>95 °C, or >200 °F) method compared with techniques such as weld overlay. Typical part configurations include piston rings, journals, conveyors, shifter forks, extrusion dies, transformer cases, ship hulls, ship tanker compartments, and suspension bridges.

Thermal spraying reduces wear and corrosion and greatly prolongs part service life by allowing use of a high-performance coating material over a low-cost base metal. Application areas of the process can be categorized as (Ref 1):

- Wear resistance
- Oxidation resistance
- Corrosion resistance
- Restoration of dimension
- Abradable clearance control
- Thermal barriers
- Electrical conductivity or resistivity
- Biomedical

More than 200 coating materials with different characteristics of toughness, coefficient of friction, hardness, and other properties are available. These materials can be grouped as follows:

- Pure metals
- Metal alloys
- Cermets
- Ceramics
- Carbides
- Polymers
- Special composite materials

All thermal spray processes rely on three basic operational mechanisms:

- Heating a coating material in either wire or powder form to a molten or plastic state
- Propulsion of particles of the heated material
- Impact of the material onto a workpiece whereby the particles rapidly solidify and adhere both to one another and to the substrate to form a dense, functional, protective coating

The particles bond to the substrate mechanically and, in some cases, metallurgically. Particle velocity, substrate roughness, particle size, material chemistry, particle temperature, and substrate temperature influence the bond strength of the coating material. The process was originally referred to as flame spraying, metal spraying, flame plating, or metallizing when it was limited to the oxygen-fuel (oxyfuel) wire spray method.

Thermal Spray Processes

Currently, five different commercially available thermal spray methods are in use:

- Oxyfuel wire (OFW) spray
- Electric arc wire (EAW) spray
- Oxyfuel powder (OFP) spray
- Plasma arc (PA) powder spray
- High-velocity oxyfuel (HVOF) powder spray

Selection of the appropriate thermal spray method is typically determined by:

- Desired coating material
- Coating performance requirements
- Economics
- Part size and portability

The oxyfuel wire spray process (also called wire flame spraying or the combustion wire process) is the oldest of the thermal spray coating methods and among the lowest in capital investment. The process utilizes an oxygen-fuel gas flame as a heating source and coating material in wire form. Solid rod feed stock has also been used. During operation, the wire is drawn into the flame by drive rolls that are powered by an adjustable air turbine or electric motor (Fig. 1). The tip of the wire is melted as it enters the flame and is atomized into particles by a surrounding jet of compressed air and propelled to the workpiece.

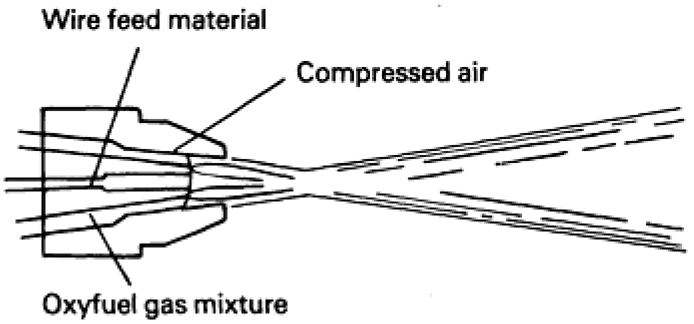

Fig. 1 Atomization of wire feedstock from the nozzle of an OFW spray gun

Spray rates for this process range from 2.3 to 55 kg/h (5 to 120 lb/h) and are dictated by the melting point of the material and the choice of fuel gas. The wire spray gun is most commonly used as a hand-held device for on-site application, although an electric-motor-driven gun is recommended for fixed-mounted use in high-volume, repetitive production work.

The OFW process is widely used for corrosion protection of large outdoor structures, such as bridges and storage tanks, and for restoration of dimension to worn machinery components. It is a good choice for all-purpose spraying. Coatings can be applied rapidly and at low cost, and a wide variety of metal coating materials are available. Typical spray materials include austenitic and martensitic stainless steels, nickel aluminide, nickel chromium alloy, bronze, Monel, babbitt, aluminum, zinc and molybdenum.

Electric arc wire spraying also applies coatings of selected metals in wire form. Push-pull motors feed two electrically charged wires through the arc gun to contact tips at the gun head (Fig. 2). An arc is created that metals the wires at temperatures above 5500 °C (10,000 °F). Compressed air atomizes the molten metal and projects it onto a prepared surface.

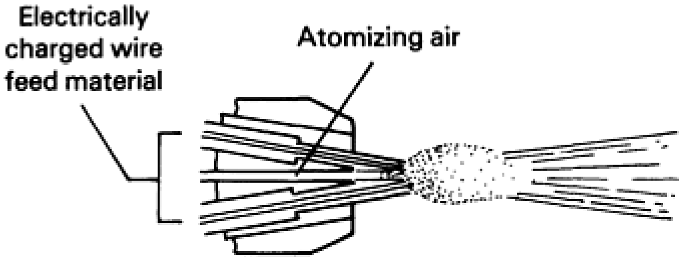

Fig. 2 Spray pattern generated by two electrically charged wires melted at the nozzle of an EAW spray gun

The EAW process is excellent for applications that require heavy coating buildup or that have large surfaces to be sprayed. The arc system can produce a spray pattern ranging from 50 to 300 mm (2 to 12 in.) and can spray at high speeds. It has built-in flexibility, allowing coating characteristics, such as hardness or surface texture, to be tailored to specific applications.

The EAW method is characterized by strong coating adhesion because of the high particle temperatures produced. Because the process uses only electricity and compressed air, it allows equipment to be moved relatively easily from one installation to another, and eliminates the need to stock oxygen and fuel gas supplies. Materials applied by the EAW method are similar to those used in the OFW process.

The oxyfuel powder spray method extends the range of available coatings and subsequent applications to include ceramics, cermets, carbides, and fusible hardfacing coatings. Using either gravity flow or pressurized feed, powder is fed into the gun and carried to the gun nozzle (Fig. 3), where it is melted and projected by the gas stream onto a prepared surface. For general-purpose spraying, the gravity-flow system is used. When exacting coating consistency and/or high spray rates are desired, the pressurized feed system is used. Oxyfuel powder guns are the lowest cost thermal spray equipment and are easiest to set up and change coating materials. The OFP method finds widest use in short-run machinery maintenance work and in the production spraying of abradable clearance-control seals for gas turbine engines.

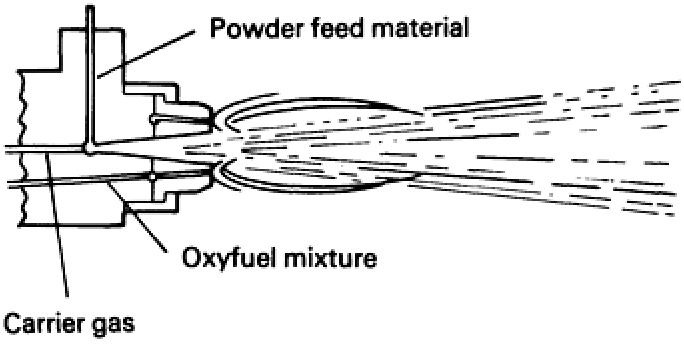

Fig. 3 Cross-sectional view of an OFP spray system showing powder feed material being transported by the carrier gas and then melted by the oxy-fuel mixture

Plasma arc powder is one of the most sophisticated and versatile thermal spray methods. Temperatures that can be obtained with commercial plasma equipment have been calculated to be greater than 11,000 °C (20,000 °F) and are far above the melting or even the vaporization point of any known material. Decomposition of materials during spraying is minimized because of the high gas velocities produced by the plasma, resulting in extremely short residence time in the thermal environment. The plasma process also provides a controlled atmosphere for melting and transport of the coating material, thus minimizing oxidation, and the high gas velocities produce coatings of high density.

The plasma gun operates on the principle of raising the energy state of a gas by passing it through an electric arc. The release of energy in returning the gas to its ground state results in exceedingly high temperatures. A gas such as nitrogen

or argon enters a direct-current arc between a tungsten cathode and a copper anode that make up the nozzle (Fig. 4). Both components are cooled by a constant flow of water through internal passages. Here the plasma gas first dissociates (in the case of nitrogen, into two atoms), followed by ionization that releases free electrons. The electrons recombine outside the electric arc, and energy is released as heat and light. In addition, frequent collisions transfer energy from the electrons to the positive ions, accelerating them until the plasma reaches a state of equilibrium. The result is a thermal plasma, in which the energy of the electrons has been turned into enthalpy, or heat content (Ref 2). At this point, powdered coating material suspended in a gas is injected into the plasma and is subsequently melted and propelled at high velocity to the workpiece. In practice, a small amount of a secondary gas, such s hydrogen or helium, is mixed with the primary plasma gas to increase operating voltage and thermal energy.

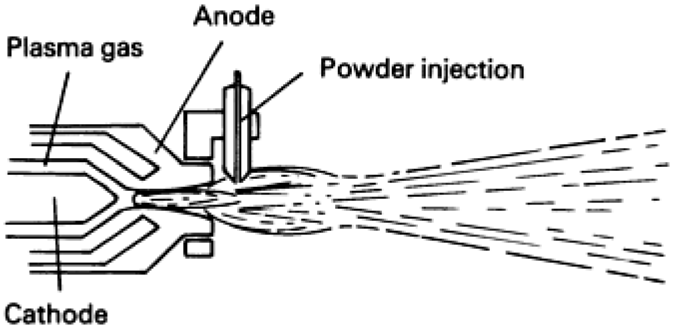

Fig. 4 Schematic of a plasma arc powder spray system showing routing of plasma gas and powder material at the output nozzle

The high temperatures and high gas velocities produced by the plasma process result in coatings that are superior in mechanical and metallurgical properties to low-velocity OFW or OFP coatings. The plasma process is particularly efficient for spraying high-quality coatings of ceramic materials, such as zirconium oxide for turbine engine combustors and chromium oxide for printing rolls. The plasma process is also readily field-portable and is thus used for large on-site applications such as power utility plant boiler tubes.

Current plasma spray technology permits fully automatic start/stop operation and closed-loop computer control for power level, plasma gas flow, and powder feed rate. System problems can be diagnosed via computer modem to the equipment manufacturer, and system performance can be documented and stored on a digital recorder or data logger. A variation of the plasma spray process is to conduct spraying within a vacuum or low-pressure chamber. Although this significantly adds to cost, the quality of metallic coatings is improved by minimizing oxides within the coating, reducing porosity, and increasing coating adhesion.

With any thermal spray powder method, the degree to which a given flame effectively melts and accelerates the powder depends on the type of coating material and the size and shape of the particles. Each particular coating material and gun combination has an optimum particle size. Particles much smaller than ideal will overheat and vaporize; much larger particles will not melt and may fall from the flame or rebound from the target (Ref 2).

The high velocity oxyfuel powder spray process (also known as the hypervelocity oxy-fuel powder spray process, the oxyfuel detonation [OFD] process, and the D-gun process) represents the state of the art for thermal spray metallic coatings. The HVOF process uses extremely high kinetic energy and controlled thermal energy output to produce very-low-porosity coatings that exhibit high bond strength, fine as-sprayed surface finish, and low residual stresses.

The HVOF process with an oxygen-fuel mixture consisting of oxygen and either acetylene, propylene, propane, or hydrogen fuel gas, depending on coating requirements. The fuel gas flows through a siphon system, where it is thoroughly mixed with oxygen (Fig. 5a). In one design, the mixed gases are ejected from the gun nozzle and are ignited. The high-velocity gases produce uniquely characteristic multiple shock diamond patterns, which are visible in the flame (Fig. 5b). Combustion temperatures approach 2750 °C (5000 °F) and form a circular flame configuration. Powder is injected into the flame axially to provide uniform heating, and powder particles are accelerated by the high-velocity gases, which typically approach a speed of 1350 m/s (4500 ft/s).

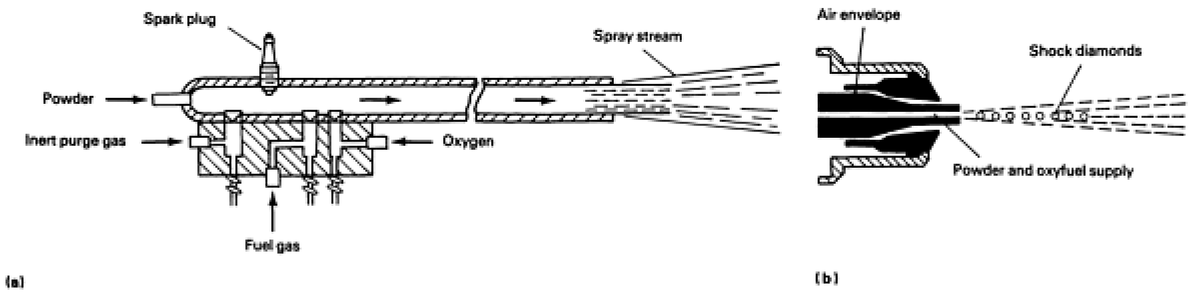

Fig. 5 Schematics showing input and output of an HVOF powder spray device. (a) Key components of an HVOF system. (b) Close-up view of HVOF spray system output

The low residual coating stress produced in the HVOF process allows significantly greater thickness capability than the plasma method, while providing lower porosity, lower oxide content, and higher coating adhesion. Coatings produced by the HVOF process also have much better machinability compared with other methods, and coating porosity has closely approached wrought materials, as verified by recent gas permeability testing. HVOF systems are available with closed-loop computer control and robotics capability.

Process Parameters

Several important factors must be considered when selecting an appropriate thermal spray method:

- Surface preparation
- Deposition rate
- Coating thickness limitations
- Bond coat materials
- Coating finishing method

Surface Preparation. Bonding of thermal spray coatings relies primarily on mechanical interlocking with the substrate material. Good surface preparation cannot be overemphasized; most coating failures can be traced to poor practice at this first step of the operation.

Nonporous surfaces should be cleaned to remove organic contamination by vapor degreasing or by washing with hot detergent solutions or steam cleaning. Porous castings may require heat treatment to pyrolize contamination at approximately 200 to 300 °C (400 to 600 °F). Cleaned parts should be uniformly abrasive blasted to achieve a white metal condition and a minimum of 6 μm (250 μin.) R_a (arithmetic average surface roughness) finish using either aluminum oxide or chilled, angular iron steel grit. The grit and air supply must be oil-free so that the cleaned surfaces are not recontaminated. Blasted parts should be handled with clean gloves and protected from shop soil until the coating operation. Spraying should be done within 2 h of blasting. Parts should be reblasted if this time interval is exceeded. Machined undercuts should have at least a 45° taper and must be cleaned and grit blasted as described above.

Deposition Rate. The coating deposition rate is limited by the method used and the melting point of the coating material. Other considerations include the deposit efficiency and target efficiency. Deposit efficiency is the quantity of coating material deposited relative to the quantity being sprayed. Target efficiency relates to the area of the spray pattern relative to the size of the part or target. Both factors influence cost.

Coating Thickness Limitations. All thermal spray coatings exhibit a degree of internal stress as a result of shrinkage from a molten state to a solid state. These stresses accumulate as the coating thickness increases and result in a shear force at the substrate interface. Ductile coating materials tend to exhibit low stress; the opposite is true for hard coating materials, such as carbides or ceramics. Also, very porous coatings exhibit lower stress than denser coatings. When the internal stress exceeds the adhesion, the coating can delaminate from the substrate or crack. Equipment manufacturers usually provide the practical thickness limit for each spray material.

Bond Coat Materials. Bond coatings form a metallurgical bond with the substrate. They include materials that react with the substrate exothermically, such as nickel-aluminum alloys, and materials that melt at high temperatures, such as molybdenum.

These materials are frequently applied as a thin coating under a poor-bonding or high-stress topcoat to enhance the adhesion provided by grit blasting alone. Bond coat materials are typically low in internal stress, and single coats are sufficient if the physical properties meet the design specifications. Selection of a particular bond coating depends on its compatibility with the spray method being used in terms of parameters such as bond strength, thermal expansion properties related to the base metal, corrosion resistance, and oxidation resistance.

Coating Finishing Method. Thermal spray coatings are finished to dimension either by single-point machining or by grinding. Hard surfacing materials such as ceramics and carbides are restricted to grind finishing, typically with diamond wheels. Thermal spray coatings are sufficiently different from the same material in wrought form that different grinding wheel and finishing tool recommendations are almost always required. Therefore, tools and wheels should not be chosen based on experience with the parent material in wrought or cast form (Ref 3).

Most thermal spray coatings exhibit some degree of porosity. However, the HVOF method produces coatings closest in machining and grinding behavior to wrought materials. In general, thermal spray coatings can be machined to 1 to 2 μm (40 to 80 μin.) R_a and ground to 0.25 to 0.5 μm (10 to 20 μin.) R_a. Many plasma spray ceramic coatings can be lapped down to 0.025 to 0.05 μm (1 to 2 μin.) R_a.

Coatings for Friction and Wear Applications

The most outstanding feature of thermal spray coatings is probably their diverse applicability. There are two primary reasons for this (Ref 4). First, materials selection is almost unlimited. Second, the thermal spray process, properly controlled, imparts very little heat to the substrate (100 to 260 °C, or 200 to 500 °F), avoiding metallurgical change, distortion, and oxidation. This allows thermal spray coatings to be applied to practically any substrate (metals, plastics, composites, etc.). Also, such coatings can often be applied to the finish machined part, a practice unthinkable with welding, heat treating, or other high-temperature processes.

Thermal spray coatings provide the design engineer with many options. They offer material properties not available in wrought metals. Coatings can be applied to selected areas rather than treating the entire part. Manufacturing costs can be reduced by eliminating unnecessary processing steps. Extraordinary performance characteristics can be designed into a part to extend its useful life, creating a new, marketable product in the process.

Thermal spray coatings provide the solution to many mechanical, electrical, and corrosion resistance problems involving metal parts and assemblies. However, there are certain applications where such coatings should not be used. Before a thermal spray coating is specified, its suitability can usually be determined according to these criteria (Ref 5):

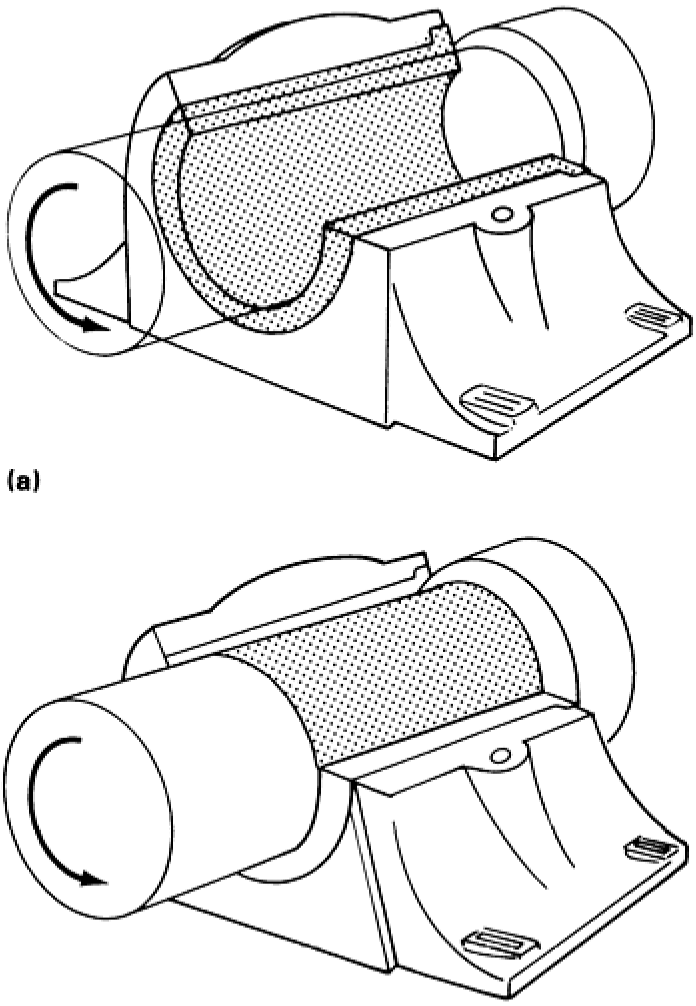
- No strength is imparted to the base material by a sprayed deposit. The component to be sprayed must, in its prepared form, be able to withstand any mechanical loading that will be experienced in service. (In a few applications, some strength can be added by a thermal spray coating; however, such uses are unusual and should be carefully tested)
- If the area on a part to be sprayed or any section of the total area will be subjected to shear loading in service, the part is not a suitable candidate for thermal spraying. Gear teeth, splines, and threads are examples
- Point loading with line contact on a sprayed metal deposit will eventually spread the deposit, causing detachment. If the deposit is on a moving component with such loading, it will fail rapidly. For example, needle and roller bearing seats, where the bearing elements are in direct contact with the sprayed deposit, may not be good thermal spray candidates
- If the base metal of a component to be treated has been nitrided, thermal spraying is not recommended unless the nitriding is first removed. Other forms of substrate hardening require special treatment, such as intensive grit blasting

Wear applications for thermal spray coatings can be categorized as adhesive wear, abrasive wear, or surface fatigue.

Adhesive Wear

Adhesive wear occurs when two surfaces slide against each other with intended motion, producing fragments from one surface that adhere to the other (Ref 6). It arises from the strong adhesive forces set up when two materials come into intimate contact. It generally occurs when lubrication is inadequate and results in metal transfer, usually called galling.

Soft bearing coatings allow the embedding of abrasive particles and also permit deformation for alignment of bearing surfaces. Adequate lubrication is required. Coatings of this type are generally low in cost, because they wear in preference to the mating surface (Fig. 6a).



(a)

(b)

Fig. 6 Cutaway views of thermal spray coated bearings showing areas that exhibit adhesive wear. (a) Soft bearing material. (b) Hard bearing material

The following performance factors apply to soft bearing coatings:

- Good lubrication must be provided or the wear rate will be excessive
- The coating must be soft enough to trap the many abrasive particles that will be carried by the lubricant
- These coatings generally have poor abrasive wear resistance
- The inherent nature of thermal spray coatings enhances their usefulness as bearing coatings. Pores act as reservoirs for lubricant; with reduced particle junctions, there is less tendency for adhesive wear

Applications and recommended materials for soft bearing coatings are listed in Table 1.

Table 1 Thermal spray coatings for friction and wear applications

Type of wear	Coating material	Coating process [(a)]	Applications
Adhesive and abrasive wear			
Adhesive wear	Soft bearing coatings:		
	Aluminum bronze	OFW, EAW, OFP, PA, HVOF	Babbitt bearings, hydraulic press sleeves, thrust bearing shoes, piston guides, compressor crosshead slippers
	Tobin bronze	OFW, EAW	
	Babbitt	OFW, EAW, OFP	
	Tin	OFW, EAW, OFP	
	Hard bearing coatings:		
	Mo/Ni-Cr-B-Si blend	PA	Bumper crankshafts for punch press, sugar cane grinding roll journals, antigalling sleeves, rudder bearings, impeller shafts, pinion gear journals, piston rings (internal combustion); fuel pump rotors
	Molybdenum	OFW, EAW, PA	
	High-carbon steel	OFW, EAW	
	Alumina/titania	OFP, PA	
	Tungsten carbide	OFP, PA, HVOF	
	Co-Mo-Cr-Si	PA, HVOF	
	Fe-Mo-C	PA	
Abrasive wear	Aluminum oxide	PA	Slush-pump piston rods, polish rod liners, and sucker rod couplings (oil industry); concrete mixer screw conveyors; grinding hammers (tobacco industry); core mandrels (dry-cell batteries); buffing and polishing fixtures; fuel-rod mandrels
	Chromium oxide	PA	
	Tungsten carbide	PA, HVOF	
	Chromium carbide	PA, HVOF	
	Ni-Cr-B-SiC/WC (fused)	OFP, HVOF	
	Ni-Cr-B-SiC (fused)	OFP, HVOF	
	Ni-Cr-B-SiC (unfused)	HVOF	
Surface fatigue wear			
Fretting: Intended motion applications	Molybdenum	OFW, PA	Servomotor shafts, lathe and grinder dead centers, cam followers, rocker arms, piston rings (internal combustion), cylinder liners
	Mo/Ni-Cr-B-SiC	PA	
	Co-Mo-Cr-Si	PA, HVOF	
Fretting: Small-amplitude oscillatory displacement applications at low temperature (<540 °C, or 1000 °F)	Aluminum bronze	OFW, EAW, PA, HVOF	Aircraft flat tracks (air-frame component); expansion joints and midspan supports (jet engine components)
	Cu-Ni-In	PA, HVOF	
	Cu-Ni	PA, HVOF	
Fretting: Small-amplitude oscillatory displacement applications at high temperature (>540 °C, or 1000 °F)	Co-Cr-Ni-W	PA, HVOF	Compressor air seals, compressor stators, fan duct segments and stiffeners (all jet engine components)
	Chromium carbide	PA, HVOF	
Erosion	Chromium carbide	PA, HVOF	Exhaust fans, hydroelectric valves, cyclone dust collectors, dump valve plugs and seats, exhaust valve seats
	Tungsten carbide	PA, HVOF	
	WC/Ni-Cr-B-SiC (fused)	OFP, HVOF	
	WC/Ni-Cr-B-SiC (unfused)	OFP, HVOF	
	Chromium oxide	PA	
Cavitation	Ni-Cr-B-SiC-Al-Mo	PA	Wear rings (hydraulic turbines), water turbine buckets, water turbine nozzles, diesel engine cylinder liners, pumps

	Ni-Al/Ni-Cr-B-SiC	PA	
	Type 316 stainless steel	PA	
	Ni-Cr-B-SiC (fused)	OFP, HVOF	
	Ni-Cr-B-SiC (unfused)	HVOF	
	Aluminum bronze	PA, HVOF	
	Cu-Ni	PA, HVOF	

(a) OFW, oxyfuel wire spray; EAW, electric arc wire spray; OFP, oxyfuel powder spray; PA, plasma arc spray; HVOF, high-velocity oxyfuel powder spray

Hard bearing coatings are highly resistant to adhesive wear. They are used where embeddability and self-alignment are not important and where lubrication is marginal (Fig. 6b).

The following performance factors apply to hard bearing coatings:

- Lubrication should be good, but is not as important as for soft bearing coatings because the high wear resistance of these materials allows them to withstand momentary unlubricated service
- Applications that require hard bearing coatings are usually characterized by high load and low speed
- Surfaces should generally be of equal hardness
- Although like coatings can be used for sliding against each other, unlike combinations are frequently used--for example, a coating running against a wrought metal. This reduces seizing and scuffing
- Wear rate generally increases with temperature

Applications for hard bearing coatings are listed in Table 1. Recommended coatings include nickel-, iron-, cobalt-, and molybdenum-base alloys, ceramics, and tungsten carbides (see Table 1).

Abrasive Wear

Abrasive wear occurs when hard foreign particles, such as metal debris, metallic oxides, and dust from the environment, are present between rubbing surfaces (Fig. 7). These particles abrade material off both surfaces. Selection of coating materials for this application should generally be based on operating temperature and surface finish requirements. The following performance factors must be considered:

- The coating must be hard. In particular, surface hardness should exceed the hardness of the abrasive grains present
- The most common abrasive is silica (sand), with a hardness of approximately 820 HK. (For comparison, tungsten carbide/cobalt composite is 1400 to 1800 HK; Al_2O_3 is approximately 2100 HK)
- Information about the abrasive--how often it is replenished, whether it is sharp and brittle, how it breaks down--is important in selecting the coating and estimating its performance
- If the system is closed, debris created by the wear process will also contribute to the wear rate and thus must also be considered
- The coating must exhibit oxidation resistance at the service temperature

Applications and recommended materials for coatings resistant to abrasive grains at low and high temperatures are listed in Table 1.

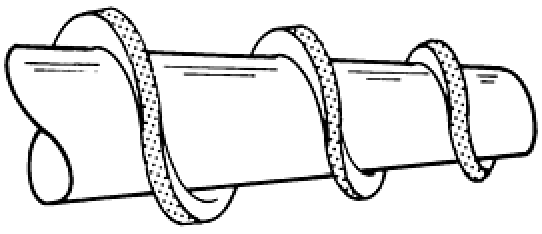


Fig. 7 Abrasive wear on the flight surfaces of a helical screw used in spiral conveyor applications

Surface Fatigue Wear

Repeated loading and unloading cause cyclic stress on a surface, eventually resulting in the formation of surface or subsurface cracks. The surface ultimately fractures and large fragments are lost, leaving pits. This phenomenon can occur only in systems where abrasive and adhesive wear are not present--for example, in systems with high surface contact loads. An area of surface must be stressed repeatedly, without constant removal of particles, to fail in fatigue. Fretting, erosion, and cavitation are typical examples of this type of wear.

Fretting. Some fretting-resistant coatings resist wear caused by repeated sliding, rolling, or impacting over a track (Fig. 8a). The repeated loading and unloading cause cyclic stresses inducing surface or subsurface cracks. Other coatings resist wear caused when contacting surfaces undergo oscillatory displacement of small amplitude (Fig. 8b). This type of wear is difficult to anticipate, because no intended motion is designed into the system. Vibration is a common cause of fretting. The following performance factors apply to coatings for fretting resistance:

- The coating must be resistant to oxidation at the service temperature. If an oxide forms, it must be tough and tenacious; a loosely adherent oxide will cause severe abrasive wear
- A surface that is free of stress, particularly tensile stress, is desirable. High-shrink coatings tend to have high surface stress and do not perform as well as low-stress coatings
- Brittle coatings fail rapidly. Tough coatings tend to perform better
- Coatings with hard particles distributed in a soft matrix are generally the most durable

Applications and recommended materials for fretting-resistant coatings are listed in Table 1.

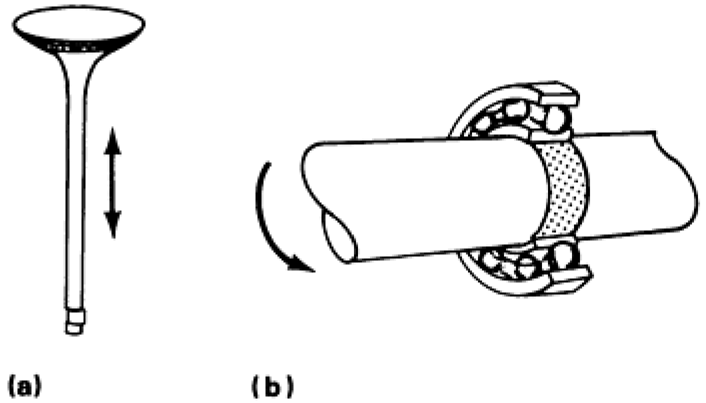

Fig. 8 Two types of fretting wear. (a) Stem and seat wear caused by the intended cyclic up-and-down motion of an engine valve. (b) Wear caused by the unplanned but unavoidable oscillatory motion of a press-fitted shaft on the inner ring of a bearing

Erosion is caused when a gas or a liquid that ordinarily carries entrained particles impinges on a surface with velocity (Fig. 9). When the angle of impingement is small, the wear-producing mechanism is closely analogous to abrasion. When the angle of impingement is normal to the surface, material is displaced by plastic flow or is dislodged by brittle failure. The following performance factors apply to erosion-resistant coatings:

- If the angle of particle impact is less than 45°, the coating selected should be harder and more abrasion resistant
- If the angle of particle impact is greater than 45°, the coating should be softer and tougher
- At high service temperatures, coatings should have high hot hardness and oxidation resistance at temperatures and environments ranging from 540 to 815 °C(1000 to 1500 °F)
- When the carrier is liquid, the corrosion resistance of the coating must be considered

Applications and recommended materials for coatings used to resist particle erosion are listed in Table 1.

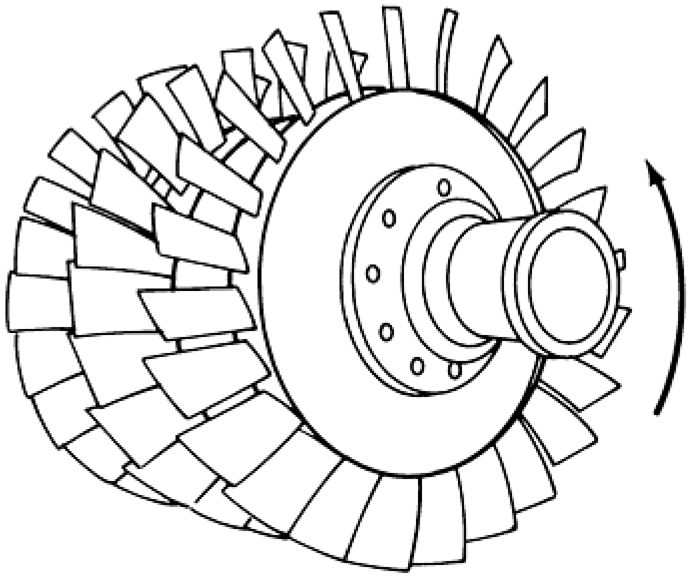

Fig. 9 Typical erosive wear of a fan blade assembly generated by the high-velocity impingement of a gas or liquid on the blade surface

Cavitation is caused by mechanical shock that is induced by bubble collapse in liquid flow (Fig. 10). Materials that resist fretting-type surface fatigue are resistant to cavitation. The most effective coating properties are toughness, high wear resistance, and corrosion resistance. The following performance factors apply to cavitation-resistant coatings:

- Relative motion between a liquid and metal surface, including bubble generation and bubble collapse, must exist for cavitation to occur
- Liquids will penetrate sprayed coatings unless fused; therefore, all coatings should be sealed
- Selection of a coating must be influenced by its resistance to the liquid used in a particular application
- Hardness is an important factor, but coatings must also be tough. Brittle coatings fail quickly
- Coatings that work harden are especially resistant to the repeated pounding of cavitation

Applications and recommended materials for coatings resistant to cavitation are listed in Table 1.

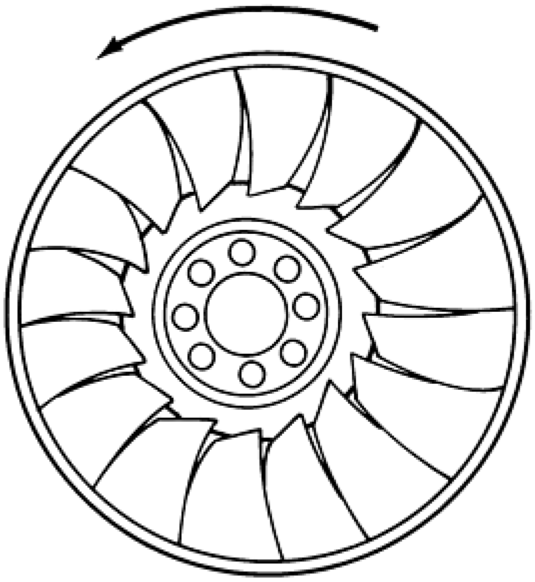

Fig. 10 **Typical surface fatigue wear produced by cavitation in a pump impeller component**

Electroplated Coatings

Rolf Weil and Keith Sheppard, Stevens Institute of Technology

Introduction

IT IS OFTEN NECESSARY to coat a material that is subject to friction and, possibly, wear. The coating can be tailored to the tribological demands of the environment and can provide a wider choice in selecting a base material to meet special requirements, such as strength or low cost.

Like other of surfaces used in tribological applications, electroplated coatings have two primary categories. Hard coatings are normally used to resist many forms of wear, such as those that involve abrasive, adhesive, and erosion process. Some degree of toughness in these coatings is often desirable, in order to resist cracking. Soft coatings are sometimes used on bearing surfaces to provide low shear strength. They are typically used at ambient temperatures and low loads.

An additional consideration in coating selection is a requirement to provide corrosion protection. Corrosive wear places particularly severe demands on the protective abilities of such a coating, because the thin surface film that is primarily responsible for limiting the corrosion kinetics is continually being worn away.

Coatings that are used to control friction and wear can be electrochemically deposited either with or without an externally applied current. Deposition without an external current is called electroless plating. For many wear applications, electrochemical deposition is the most rapid and economical means to apply coatings ranging from 10 to 500 μm (0.4 to 20 mils) in thickness (Ref 1).

Adhesion to the substrate is a very important requirement of all coatings. Because adhesion primarily depends on the cleanliness of the substrate surface to be coated, proper pretreatment of the substrate is usually necessary.

Deposition Fundamentals

Electroplating is the coating of an electrically conducting surface by application of an electrical potential in a suitable solution that contains the ions of the metals to be deposited. The electrode to be coated is the cathode. The counter-electrode, the anode, can be of the soluble type, so that it supplies metal ions to the solution. Alternatively, the anode can be insoluble, in which case the ions of the metals to be deposited must be continuously or periodically added to the plating solution to compensate for the depletion.

The deposition rate depends primarily on the current density. If all supplied electrons reduce the metal ions, then the deposition rate can be readily calculated from Faraday's law, which states that 96,500 coulombs (1 Faraday) deposit 1 gram (0.035 oz) equivalent weight (atomic weight divided by valence). However, hydrogen evolution or other secondary reactions may use some of the current supplied. Thus, only a fraction of the supplied electrons reduces the metal ions. In this case, the plating efficiency is less than 100%. (The plating efficiency is the ratio of the metal yield to that calculated from Faraday's law, which assumes that there are no other reactions.)

The microstructures of electrodeposits, which to a large extent determine their properties, depend on a number of factors. These factors include the microstructure of the surface to be coated, the plating conditions (that is, the current density), the temperature and composition of the plating solution, as well as the degree and type of agitation. The composition and the pH of the plating solution in the vicinity of the cathode (which generally differs from that of the bulk) can have a large effect on the structure and properties of the deposit. In the absence of significant surface inhibition, it is possible for the deposit to reproduce the structure of the substrate surface. However, even minute quantities of certain substances can greatly affect the structure. These substances may be intentionally added to the plating solution or be present as impurities from the water, chemicals, or secondary reactions. Foreign substances can alter the grain orientation by being preferentially adsorbed on certain crystal planes. Then, grains with other planes exposed on their surfaces can grow preferentially until they essentially compose the entire deposit, thereby producing a fiber texture, that is, most of the grains have same crystallographic direction normal to the surface.

The adsorption of some foreign material can greatly reduce the grain size. These materials impede grain growth, thereby requiring almost continuous renucleation. Some addition agents are present in plating solutions to level the deposit surface, that is, to make it smoother than the substrate. They do so by being preferentially adsorbed on asperities. By blocking growth on the asperities, the recesses receive most of the depositing metal, thereby producing a smoother surface.

High internal stresses, particularly of the tensile type, can adversely affect the wear properties of electrodeposits. They can arise from the lattice misfit between the substrate and an epitaxial deposit, from the coalescence of crystallites, or from the diffusion of hydrogen out of the surface layers. These stresses can be large enough to cause cracking, as is the case in some chromium deposits. Most electrodeposits are also characterized by a high dislocation density, which results in strength, hardness, and ductility values that are similar to those of the same metal in the cold-worked condition.

Pulse plating has been used to enhance the tribological properties of electrodeposits. Generally, a square-wave current pulse is employed. The current is on for a certain time period and off for another. The ratio of the time to the sum of the on and off times is called the duty cycle. By varying the pulse frequency, the duty cycle, and the current density, the structure and properties of electrodeposits can be beneficially changed.

Electroless plating is an autocatalytic reaction in which a reducing agent supplies an internal current. The advantages of electroless plating are that nonmetallic substrates can be coated and the deposit thickness is uniform. The autocatalytic

reaction has to be activated on some surfaces, particularly those that are nonmetallic. Thus, the areas to be plated can be controlled by specific activation. The disadvantages are a slow deposition rate and a higher cost. It is also necessary to maintain the composition of the plating solution by continuous or frequent additions of the depleted chemicals and removal of the impurities.

Wear-resistant composite can be produced by the codeposition of fine particulate matter. Hard particles, such as diamond, silicon carbide, and aluminum oxide, are kept in suspension by agitation and become occluded in the deposit. Solid lubricants, such as polytetrafluoroethylene (PTFE) particles, have also been codeposited. As much as 30 vol% of the particles can be attained in both electrodes and electroplated coatings (Ref 2).

In some applications, only limited areas of a component are subjected to wear. If the deposition of precious metals is involved, then it may be economically desirable to coat these areas selectively. Such limited coverage can be achieved by jet plating, laser-enhanced and laser-jet plating, and by physically masking off areas not to be plated, as in photolithography (Ref 3).

In jet plating, a fine jet of the plating solution is directed onto the areas to be coated. Because the current is constrained within the jet, only the areas where it is applied become coated. The jet also provides rapid ion transport to the depositing surface and therefore permits to the deposition rates. In laser-enhanced plating, the heating effect of the laser enhances mass transport locally. It can also influence the deposition kinetics such that metal is not plated outside of the heated area. Laser-jet plating, which is a combination of jet and laser-enhanced plating, can provide improved deposit characteristics. The jet then acts as a waveguide for the laser.

The principal electrochemically deposited materials used in tribological applications are chromium, nickel, and both precious and soft metals. The characteristics of each type of deposit are described in this article. References 4, 5, 6, 7, 8, 9, 10, 11 provide additional information relevant to electrochemically deposited metals and alloys used in tribological applications.

Chromium

Hard chromium coatings are widely used because of their low coefficient of friction and good wear properties. They are deposited at higher temperatures and current densities than decorative chromium. The plating solution for hard chromium has a lower ratio of chromic oxide to sulfuric acid (the main constituents of the solution) than that used for decorative coatings. The thickness of hard chromium deposits varies from about 0.1 to 100 μm (0.004 to 4 mils), whereas decorative thicknesses usually range from about 0.1 to 0.2 μm (4 to 8 μin.). Very strict antipollution to regulations govern the discharge of solutions containing hexavalent chromium ions, which are used for hard-chrome plating. Therefore, plating solutions that contain mostly trivalent chromium ions are of interest. These solutions generally contain formic acid or one of its salts. Carbon will deposit in these solutions. The deposits can therefore be heat treated to precipitate a chromium carbide.

The hardness of hard chromium varies from about 900 to 1100 on the Knoop and Vickers hardness scales. These values are considerably higher than the hardness of bulk chromium. Deposits from trivalent solutions are softer than those that are plated from hexavalent chromium solutions. However, after heat treating at about 700 °C (1290 °F), a hardness comparable to that of hard chromium can be achieved (Ref 12).

Chromium deposits are characterized by high internal tensile stresses that can reach 1000 MPa (145 ksi). These stresses can reduce the fatigue properties of coated components. Hydrogen is also codeposited with chromium and can diffuse into components, causing hydrogen embrittlement. Heat treatments are typically required to relieve the stresses and hydrogen effects, but can reduce the hardness.

The coefficients of friction of hard chromium against hard materials are generally the lowest of any electrochemically deposited coatings. The actual values vary considerably, depending on the test method, the mating surfaces of the materials, and the degree of lubrication. Some values of static and sliding coefficients of friction are listed in Table 1. The static coefficient is calculated from the force to initiate movement of one component of a couple against the other. The force to maintain movement enters into the calculation of the sliding coefficient. It is important to note that only coefficients of friction obtained under the same conditions can be compared. The values should not be considered as absolute.

Table 1 Coefficients of friction

Couple	Static coefficient	Sliding coefficient
Chromium-plated steel versus itself	0.14	0.12
Chromium-plated steel versus steel	0.15	0.13
Steel versus steel	0.30	0.20

Source: Ref 13

The wear rates of hard chromium can vary greatly, depending, again, on the type of test. The rates also vary with the mating material and whether adhesive or abrasive wear predominates. Some dry abrasive wear data from a Taber abrasion test for three chromium deposits labeled CrA, CrB, and CrC are shown in Fig. 1. The Taber test measures, for a certain number of cycles, the weight loss that results from abrasion with resilient, abrasive wheels at a load of 9.8 N (11 kgf). Figure 1 shows that deposit CrC had less wear than deposit CrA.

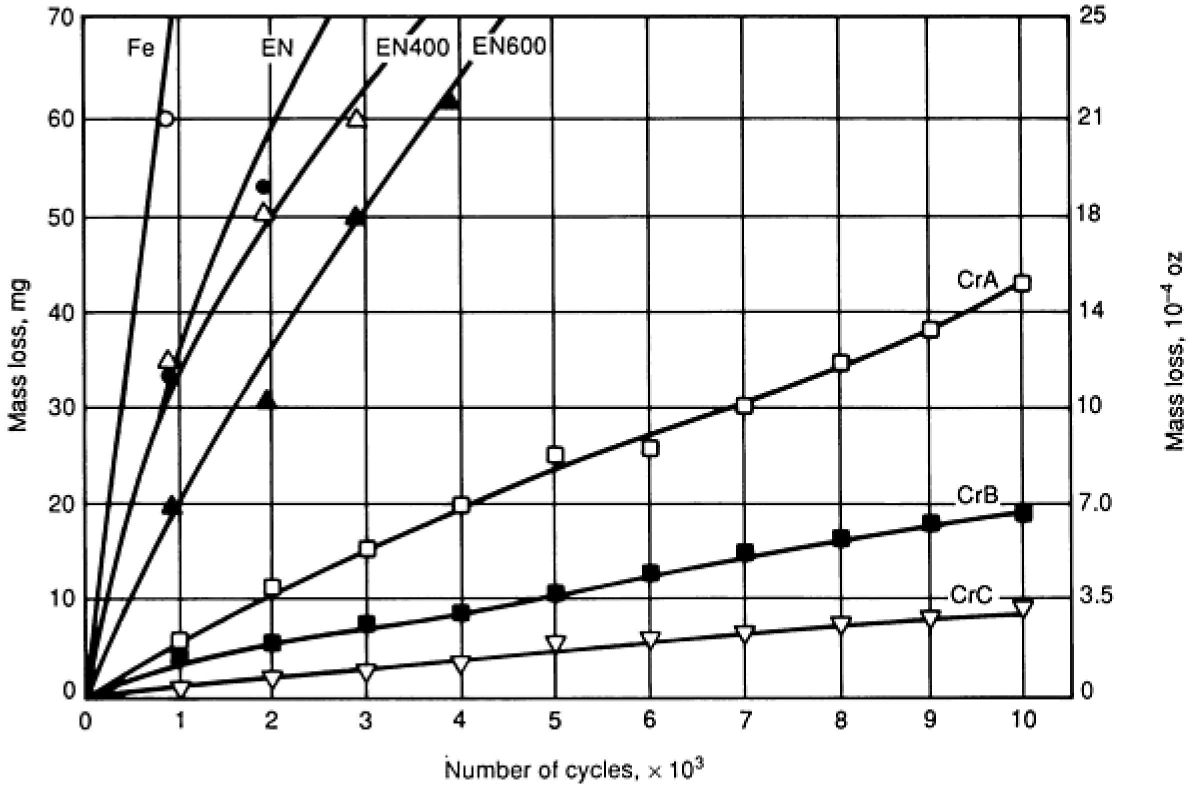

Fig. 1 Effect of number of cycles on mass loss in the Taber abrasion test for uncoated steel substrate (Fe), three chromium deposits (CrA, CrB, CrC), and three electroless nickel deposits: as-plated nickel (EN), heat treated at 400 °C (750 °F) (EN400), and heat treated at 600 °C (1110 °F) (EN600). Source: Ref 1

Figure 2 represents data obtained in a Falex wear test for the same three chromium deposits. In this test, a pin is rotated between two V-shaped blocks. Deposit CrA showed less wear than deposit CrC, illustrating the effect of a lubrication test method on the results. Figure 1 also shows that the chromium coating improved the abrasion resistance of the steel substrate. The hardest chromium deposits do not necessarily exhibit the least wear. The low friction coefficients and good wear properties of chromium have been attributed to a self-healing Cr_2O_3 film that forms on the surface. In general, hard chromium has a lower wear rate than either electroplated or electroless nickel, which are the two competing materials. This effect is also illustrated in Fig. 1 and 2.

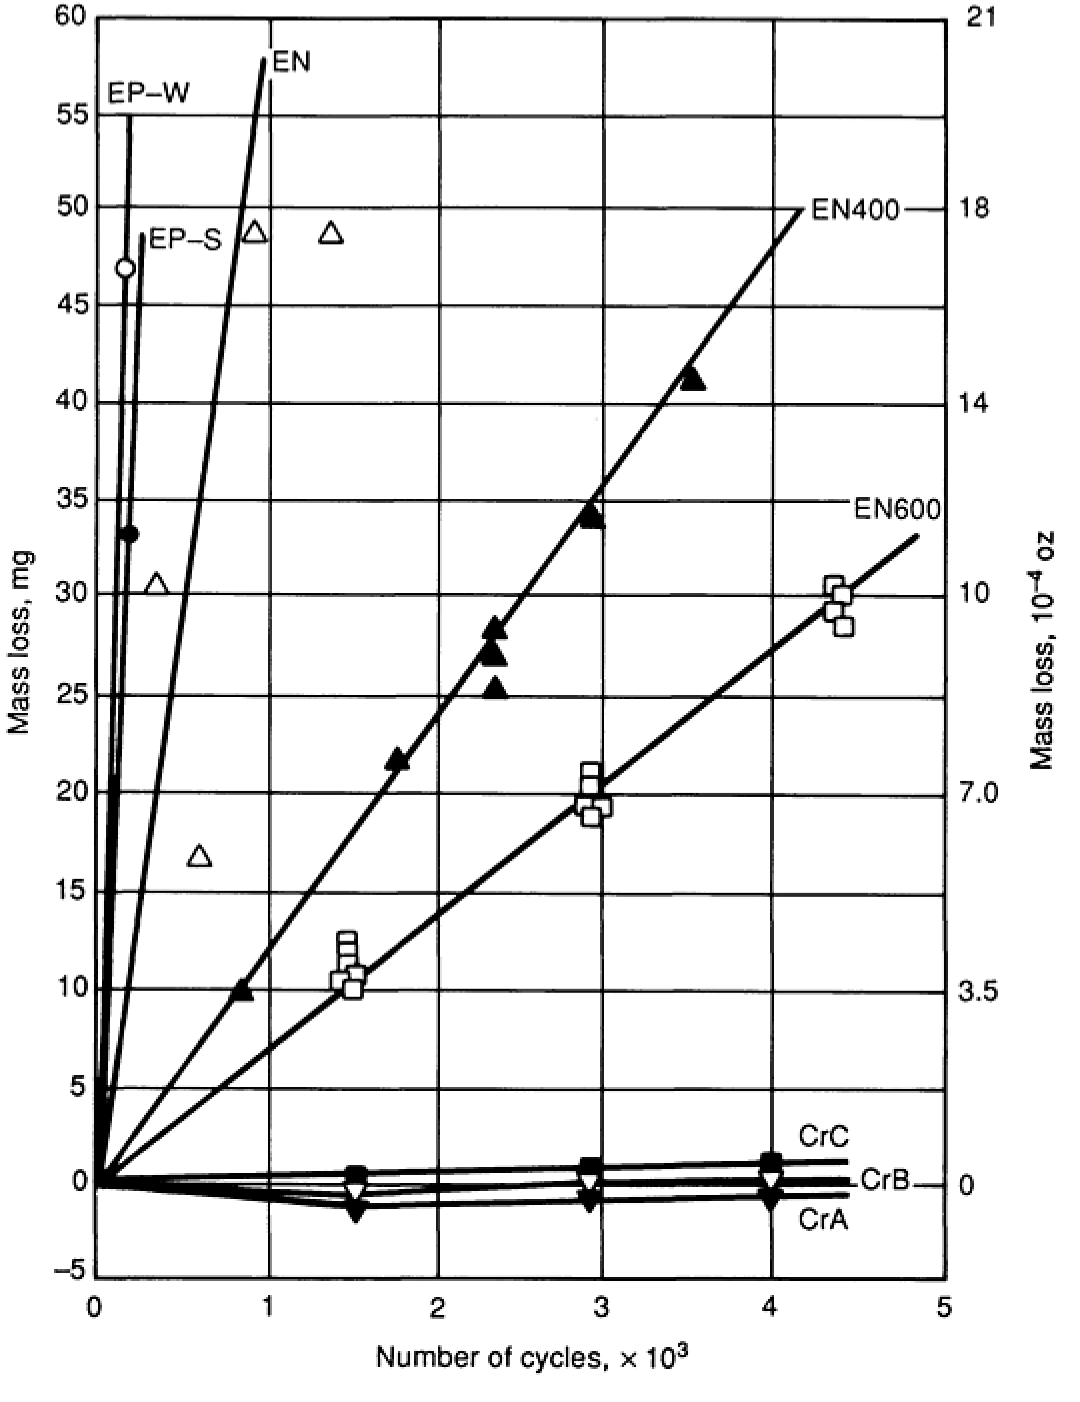

Fig. 2 Effect of number of cycles on mass loss of plated pin versus steel blocks in a Falex test for same three chromium deposits (CrA, CrB, CrC) and same three electrodes nickel deposits (EN, EN400, EN600) shown in Fig. 1. Effects on two electroplated nickles from a sulfamate solution (EP-S) and a Watts solution (EP-W) are shown. Source: Ref 1

Under corrosive wear conditions, chromium coatings do not protect substrates if they crack in response to high internal stresses. Pulse plating can reduce the internal stresses and the resulting cracking of the deposit. The effects of pulse plating and deposition temperature on the wear rate of chromium deposits are shown in Fig. 3. The improve wear resistance at higher pulse frequencies and temperatures corresponds to increases in hardness. The wear resistance in some applications can also be improved by the inclusion in the deposit of hard particles or those of a solid lubricant (Ref 15).

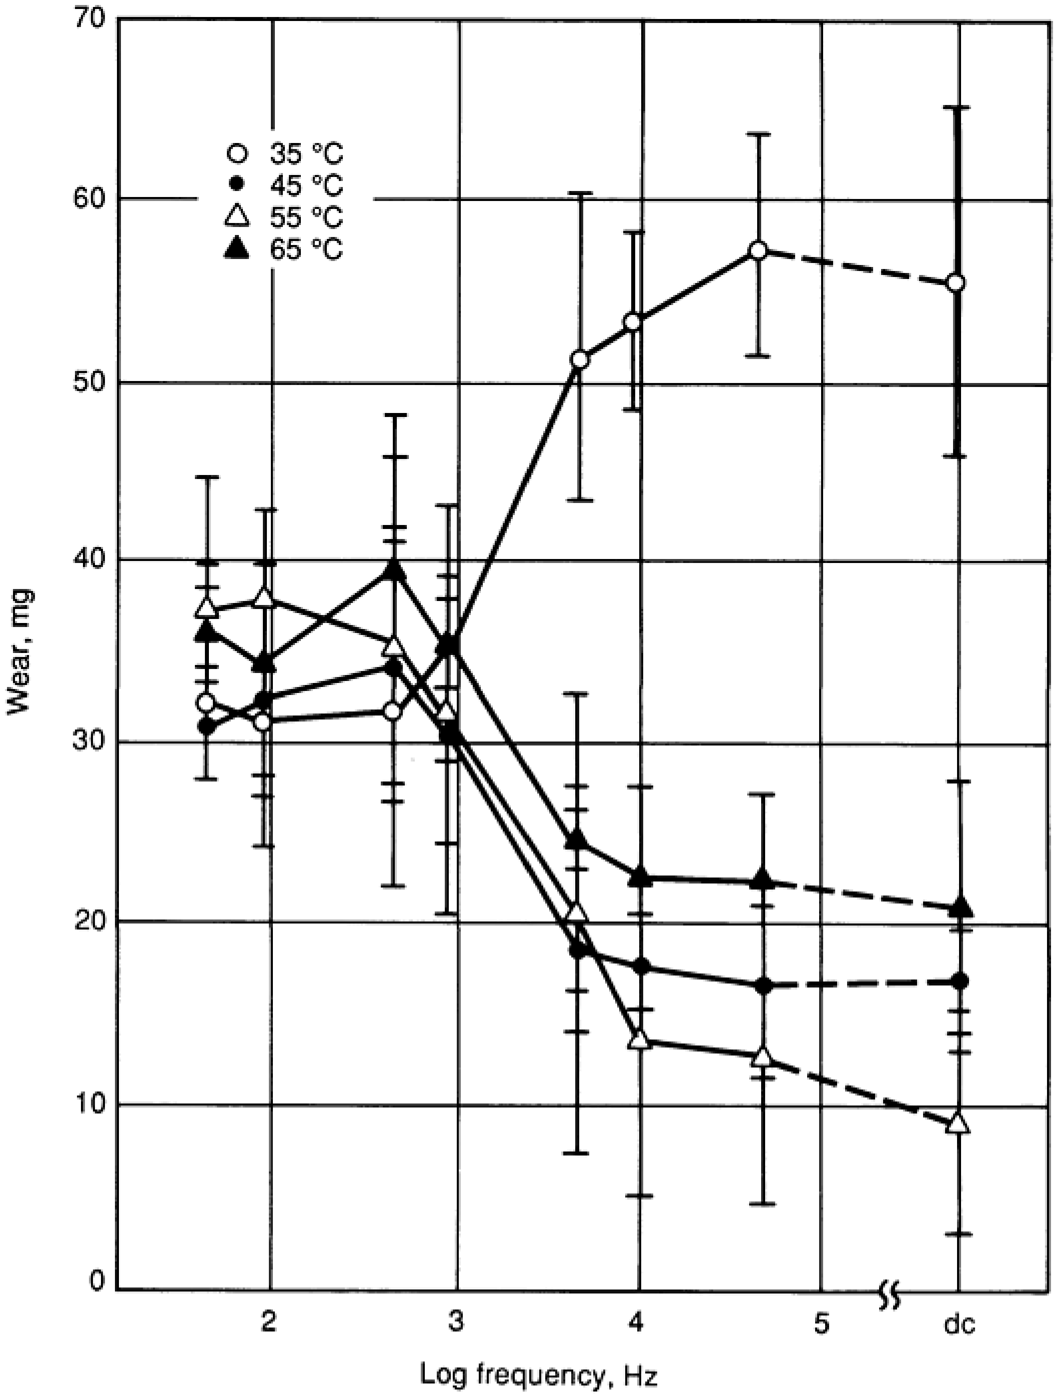

Fig. 3 Effect of pulse frequency and solution temperature on mass loss of chromium deposits in a Taber abrasion test. dc, direct current. Source: Ref 14

Chromium is widely used for wear resistance in automotive and aircraft components, such as pistons and shock absorbers (Ref 13). Other applications include coatings on drills, taps, dies, extrusion screws, and rolls. The wear resistance of gun barrels can also be improved by chrome plating. Salvaging of worn parts by chromium electrodeposition is an important industrial application.

Most of these applications require relatively thick chromium deposits. Thick deposits have a nodular surface structure, which is shown in Fig. 4. Cracks that are due to high internal stresses are also visible. The nodular structure is too rough for some applications and therefore requires a mechanical finishing operation. Machining tools are usually plated with a thin chromium deposit, which is smooth and does not need to be finished (Ref 16).

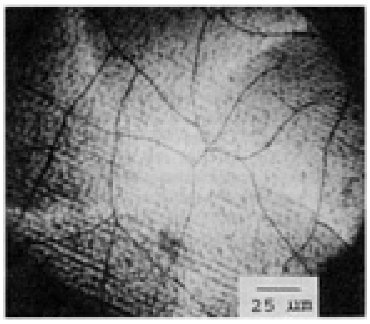

Fig. 4 Optical micrograph of electrodeposited chromium showing nodular structure and cracks

Electroplated Nickel

The most widely used solution for plating nickel for wear applications is the Watts solution. Its main components are nickel sulfate, nickel chloride, and boric acid. Organic addition agents in the plating solution can increase the hardness and wear resistance mainly by decreasing the grain size. Nickel usually is deposited with a tensile internal stress. Some sulfur compounds can cause the stress to become compressive, but also make the deposit more brittle, especially under elevated-temperature conditions. The nickel sulfamate plating solution produces low-stress deposits. It is possible to codeposit such metals as tungsten and molybdenum with nickel, even though they cannot be plated alone in aqueous solutions. Inclusion of hard particles or those of solid lubricants can also improve the wear or friction properties of electroplated nickel.

Improved wear resistance resulting from the incorporation of SiC particles is shown in Fig. 5. In the test on which the data of Fig. 5 are based, a plated block was pressed against a lubricated steel ring. Further improvement that was done to phosphide precipitates in heat-treated Ni-P-SiC coatings is also seen in this figure.

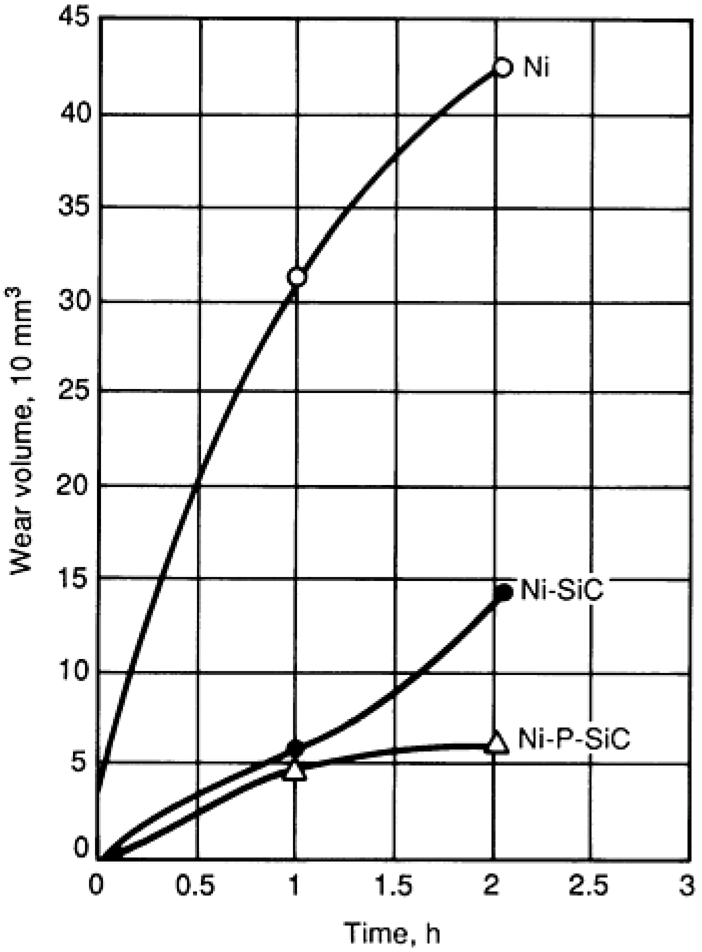

Fig. 5 Effects of codeposited SiC particles and phosphide precipitates on wear of electrodeposited nickel heat treated for 1 h at 400 °C (750 °F). Source: Ref 17

The hardness of nickel deposits can vary from about 150 to 500 on the Vickers scale. The hardness depends on the plating conditions, that is, current density, solution pH and temperature, and composition. Pulse plating can increase the hardness. The coefficient of friction and wear rates of electroplated nickel are generally greater than those of chromium. The lower wear rates of electroless, compared with electroplated, nickel can be seen in Fig. 1 and 2. The widest use of electroplated nickel for wear applications is as an undercoat for chromium. If thick deposits are needed, for example, in building up heavily worn parts, it is usually not practical to do so using only chrome plating, because of its low current efficiency ad high internal stress. In such cases, most of the deposit thickness is composed of nickel, with chromium constituting only a thin outer layer.

Under corrosive conditions, chromium may not protect the substrate, because of its cracks, but a nickel undercoat will. There are some applications of electrodeposited Ni-W, Ni-Mo, and Ni-Cr alloys that are hard and wear resistant. These alloys also offer good corrosion protection.

Electroless Nickel

The tribological and associated properties of electroless nickel were extensively discussed by Weil and Parker (Ref 18). The reducing agents for electroless nickel are sodium hypophosphite, sodium borohydride, or organic aminoboranes. When sodium hypophosphite is the reducing agent, the deposit generally contains between 3 and 11 wt% phosphorus. The boron contents of electroless nickel range from 0.2 to 4 wt% and from 4 to 7 wt% when the reducing agents are an aminoborane and sodium borohydride, respectively.

As-deposited electroless nickel is a supersaturated solid solution because the equilibrium solid solubility of boron or phosphorus in nickel is essentially zero. However, the second phase cannot form, because the time interval between the

deposition of successive layers is too short for the necessary diffusion. The structure of the deposit changes from microcrystalline to amorphous, with increasing alloy content. The second phase, which is Ni_3P Ni_3B, can form on annealing and result in precipitation hardening.

Electroless nickel can be heat treated to hardnesses comparable to those of electrodeposited chromium. The maximum hardness can be attained in 1 h at about 400 °C (750 °F) or 10 h at 260 °C (500 °F). The hardness of as-plated Ni-P alloys varies from 500 to 650 on the Vickers scale. As-plated Ni-B deposits are generally harder than the Ni-P ones. The ability of electroless nickel deposits to maintain their hardness under elevated-temperature service conditions increases with increasing phosphorus or boron content, but decreases rapidly above 385 °C (725 °F). Nickel-boron coatings tend to better withstand wear at elevated temperatures and are therefore more widely used under these conditions.

Coefficients of friction of electroless nickel in the as-deposited condition (EN) and heat treated at 400 °C (750 °F) (EN400) and at 600 °C (1110 °F) (EN600) are listed in Table 2. They are compared to the three chromium alloys depicted in Fig. 1 and 2. The counter surfaces were diamond and plain carbon steel. The coefficients friction of the electroless nickels are higher than those of the chromium deposits. It should be noted that the values for the chromium deposits against steel are considerably higher than those listed in Table 1, again highlighting the fact that only data obtained under identical conditions can be compared.

Table 2 Coefficients of friction of chromium versus electroless nickel

Coating	Coefficients of friction	
	Counterface diamond	**Counterface plain C steel (080M40)**
CrA	0.040	0.88
CrB	0.035	0.82
CrC	0.030	0.81
EN	0.180	0.96
EN400	0.300	0.95
EN600	0.060	0.90

Source: Ref 1

Electroless nickel is most frequently used in wear applications in the precipitation-hardened condition. The improved abrasion and wear resistance after heat treating is evident from Fig. 1 and 2. Parker (Ref 19) found that the heat-treated electroless nickel exhibited smaller weight losses for comparable numbers of cycles than are shown in Fig. 1. Although the greatest hardness was obtained by heat treatment at 400 °C (750 °F), the electroless nickel that was heat treated at 600 °C (1110 °F) showed the least wear. However, the corrosion resistance of as-plated Ni-P coatings, which is one of the main reasons for their use, deteriorates upon heat treating to the maximum hardness, because of cracking. Therefore, under corrosive wear applications, it may be prudent for forgo the higher hardness.

The widest use of electroless nickel for both corrosion and wear resistance is in valves that control the flow of either liquids or gases. Other uses (Ref 20) of electroless nickel in wear applications include aluminum piston heads, aircraft engine shafts, components of gas turbines and engine mounts in the aircraft industry, and such automotive parts as differential pinion ball shafts, fuel injectors, ball studs, disk brake pistons, transmission thrust washers, knuckle pins, and hose couplings.

In mining applications and associated material-handling equipment, where abrasive wear conditions prevail, electroless nickel has been substituted for hard chromium. A very important application of electroless nickel is the salvage of worn surfaces, especially because it is possible to coat only specific areas. Thus, little or no subsequent machining or grinding is required. The inclusion in electroless-nickel deposits of hard or solid-lubricant particles can also improve their tribological properties. The effect of these particles on the wear of electroless nickel is similar to that shown in Fig. 5.

Precious Metal Deposits

Separable electrical connectors are not only subjected to wear, but must maintain low contact resistance. Electrodeposited gold from a cyanide plating solution is most widely used, because it does not form on oxide surface film of high electrical resistivity. Soft gold deposits wear poorly. The addition of cobalt ions to the plating solution is the most frequent means

used to increase the hardness of gold. However, cobalt additions reduce the ductility of the deposits. These effects appear to be due primarily to grain-size reduction. The addition of cobalt is accompanied by the codeposition of fine polymer particles that are cobalt-cyanide compounds.

Gold plate from solutions that contain nickel ions is also used for separable connectors. An additive-free, gold-plating solution based on phosphoric acid results in deposits that have properties comparable to those of the cobalt-hardened deposits (Ref 21). To prevent interdiffusion of gold and the substrate, which is usually copper, a layer of nickel is often deposited as a barrier.

Palladium, Pd-Ag, and Pd-Ni have been substituted for gold (Ref 22), primarily in an effort to reduce costs. Polymerization of organic air pollutants can occur on the catalytically active palladium surface under tribological conditions and result in a film of high electrical contact resistance. Alloying reduces polymer formation. Other measures can also be taken, including coating one or both mating surfaces with a thin gold layer (250 μm, or 10 mils) or using higher contact forces. Fretting corrosion, which results from the small-amplitude movements of the mating surfaces that are often due to vibrations or different thermal expansion rates, can cause a thin gold deposit to wear through and the polymer film to form.

The Knoop hardness is about 200 for cobalt-hardened gold and about 180 for gold from the additive-free phosphate solution. On the same scale, 25-karat gold has a hardness of only about 50. Table 3 compares the characteristics of various precious metal contacts (Ref 23). A low ductility, that is, less than 1% elongation in a tension test, is desirable for gold deposits to reduce prow formation, which is the build-up of a lump of work-hardened metal. Antler (Ref 24) has reviewed the tribology of electronic connectors.

Table 3 Plated contact metallurgical properties

Properties	Gold		Palladium	Palladium-nickel
	Soft	**Hard**		
Resistivity, μΩ · cm	2.1-2.3	3.8-4.2	9.9-10.7	n/a
Contact resistance, mΩ	0.7	1.4	3.5	2.0[a]
Hardness, kgf/mm^2	60-100	130-200	200-400	500-650
Density, g/cm^3[b]	19.3	17	12	11
Corrosion resistance	E	E	VG	E[a]
Solderability	E	P	G	VG[a]
Wear resistance	P	G	VG	E[a]
Cost[b] (equal thickness)	. . .	. . .	30% of Au	20% of Au

E, excellent; VG, very good, G, good; P poor.

(a) With gold flash.

(b) Approximate values.

Soft Metals

Electrodeposited soft metals such as tin, lead-tin, and silver alloys are used as bearing coatings. Tin and silver deposits prevent galling, especially during start-up. The codeposition of 3.4 to 3.6% Pb with silver provides excellent antiseizure coatings for bearings (Ref 25). Silver alloys are used for elevated-temperature solid lubrication. Separable electrical contacts have also been coated with electrodeposited Pb-Sn. In this case, friction results in the removal of a high-resistivity surface film. An alloy of lead with from 4 to 10% tin, and sometimes containing copper, is used for sleeve-bearing overlays (Ref 26). Lead alloyed with indium is an excellent bearing material that also possesses good corrosion resistance. However, it is more expensive than alloys of lead and tin. Electrodeposits for bearings are reviewed in greater detail by Eastham and Crooks (Ref 27).

Magnetic Materials

Electroless and electrodeposited magnetic alloys, such as Permalloy (Ni-Fe) and various cobalt alloys (Co-P and Co-Ni-P), are used in advanced magnetic storage technologies, such as hard memory disks for computer systems. Electroless nickel that has a high enough phosphorus content (greater than 7 wt%) to be amorphous and therefore nonmagnetic is commonly used as an underlayer for magnetic coatings. These storage systems represent a demanding tribological environment, because of the need to maintain minimal separation between the read/write heads and the storage media. This close proximity is necessary to maximize information storage density. It has been suggested that the resources lost to friction and wear at the head-media interfaces in magnetic storage amount to about 1% of the U.S. gross national product (Ref 28). Even if this figure were an overstatement, it does indicate the scale of the problem.

Because it is necessary to limit the wear of the head and disk materials, the very thin magnetic layer on storage disks is normally coated with a thin wear-resistant and/or lubricating layer. The coating also affords corrosion resistance. Electroplated rhodium, which has properties similar to hard chromium, has been used for this purpose. However, it is now more typical to employ such coatings as silicates or the so-called diamond-like hydrogenated carbon (Ref 3). In addition to the coating, a lubricating layer may also be necessary.

Moisture and ionic contaminants, such as salts, can lead to corrosion. Porosity in the protective coating can allow corrosion of the magnetic layer and undercoat. The primary strategy is to minimize corrosion by producing pore-free protective layers. However, corrosion resistance can be improved by incorporating elements such as chromium into the magnetic layer, as long as potentially detrimental effects on the magnetic properties can be ameliorated. In practice, it is possible to codeposit chromium by vapor phase methods. Presently, the codeposition of chromium in cobalt magnetic films represents a challenge to electrodeposition technology, along with the provision of a self-lubricating surface (Ref 3). It is also apparent that the need to maintain submicron spacing between the magnetic layer and the heads in advanced storage systems requires much better control of the electrochemical plating processes than is generally exercised.

PVD and CVD Coatings

R.F. Bunshah, University of California at Los Angeles

Introduction

VAPOR DEPOSITION PROCESSES can principally be divided into two types (Ref 1):

- *Physical vapor deposition* (PVD) processes, which require creation of material vapors (via evaporation, sputtering, or laser ablation) and their subsequent condensation onto a substrate to form the film
- *Chemical vapor deposition* (CVD) processes, which are generally defined as the deposition of a solid material from the vapor phase onto a (usually) heated substrate as a result of numerous chemical reactions

PVD and CVD processes can be classified as shown in Table 1.

Table 1 Classification of physical vapor deposition (PVD) and chemical vapor deposition (CVD) processes on the basis of material deposited on substrate

Process	Metals		Compounds	
	Basic	**Hybrid**	**Basic**	**Hybrid**
Physical vapor deposition				
Conventional	Evaporation deposition	Ion plating	. . .	. . .
	Sputter deposition	. . .	. . .	. . .
Plasma-assisted (PAPVD)	. . .	. . .	Activated reactive evaporation (ARE)	Reactive ion plating (RIP)
	. . .	. . .	Reactive sputtering (RS)	. . .
Chemical vapor deposition				
Conventional	Thermal	. . .	. . .	. . .
Plasma-assisted (PACVD)	. . .	. . .	rf excitation	. . .
	. . .	. . .	Microwave excitation	. . .

Table 2 shows selected parameters of basic PVD and CVD processes. In general, CVD processes have the advantage over PVD processes of good throwing power, while PVD processes have higher deposition rates than those in CVD processes.

Table 2 Selected parameters of basic PVD and CVD processes

Parameter	Physical vapor deposition		Chemical vapor deposition
	Evaporation	**Sputtering**	
Mechanism of production for depositing species	Thermal energy	Momentum transfer	Chemical reaction
Deposition rate	Can be very high (up to 7.5×10^5 Å/min)	Low except for pure metals (for example, copper, 10^4 Å/min)	Moderate (200-2500 Å /min)
Depositing specie	Atoms and ions	Atoms and ions	Atoms
Throwing power	Poor line-of-sight coverage except by gas scattering	Good, but nonuniform thickness distribution	Good
Metal deposition	Yes	Yes	Yes
Alloy deposition	Yes	Yes	Yes
Refractory compound deposition	Yes	Yes	Yes
Energy of deposited species	Low (1.6×10^{-20} to 8.0×10^{-20} J, or 0.1 to 0.5 eV)	Can be high (1.6×10^{-19} to 1.6×10^{-17} J, or 1 to 100 eV)	Can be high with plasma-assisted CVD
Bombardment of substrate/deposit	Not normally	Yes	Possible
Growth interface perturbation	Not normally	Yes	Yes (by rubbing)
Substrate heating (by external	Yes, normally	Not generally	Yes

As with all processes, the user is concerned with the process itself as well as the resulting microstructures and properties of the product. In order to understand various vapor deposition processes, one has to model them in terms of three steps (Ref 1):

- *Step 1:* creation of vapor phase specie (a material can be put into the vapor phase by evaporation, sputtering, laser ablation, electrolyte, chemicals, plasma spray, D-gun, gases, vapors, and so on)
- *Step 2:* transport from source to substrate (the vapor species are transported from the source to the substrate with or without collisions between atoms and molecules; during transport, some of the vapor species can be ionized by creating a plasma)
- *Step 3:* film growth on the substrate (this process involves the condensation of the vapor species onto the substrate and subsequent formation of the film by nucleation and growth processes; the nucleation and growth processes can be strongly influenced by bombardment of the growing film by ionic species, resulting in a change in microstructure, composition, impurities, and residual stress)

The degree of independent control of these three steps determines the versatility or flexibility of the deposition process. For example, these three steps can be independently controlled in PVD processes and therefore give a greater degree of flexibility in controlling the structure, properties, and deposition rate, whereas all of the three steps take place simultaneously at the substrate and cannot be independently controlled in the CVD process. Thus, if a process parameter such as the substrate temperature that governs the deposition rate in chemical vapor deposition is initially chosen, the user is limited to the resultant microstructure and properties obtained.

Physical Vapor Deposition Processes

The basic PVD processes fall into two general categories: (1) sputtering and (2) evaporation. PVD techniques are used for a wide variety of applications, from decorative uses to deposition of high-temperature superconducting films. The thickness of the deposits can vary from angstroms to millimeters. A very high deposition rate (25 μm/min, or 1000 μ in./min) has been achieved with the advent of electron beam (EB) heated sources. A very large number of inorganic materials (metals, alloys, compounds, and mixtures) as well as some organic materials can be deposited using PVD technologies. Ion plating is a hybrid PVD process because it is defined as an atomistic film deposition process in which the substrate surface and the depositing film is subjected to a flux of high-energy particles that is sufficient to cause changes in the interfacial region between the film and the substrate in addition to changes in the properties of the deposited film as compared to a nonbombarded film. These changes may be in the adhesion of the film to the substrate or in morphology, density, or stress. The source of the depositing species can be evaporation, sputtering, gases, or vapors.

Sputter Deposition

Sputtering is the phenomena of momentum transfer from an indirect energetic projectile to a solid or liquid target resulting in the ejection of surface atoms or molecules. In the sputter deposition process, the target (a source of coating material) and the substrate are placed in the vacuum chamber and evacuated to a pressure typically in the range of 13 to 0.013 mPa (0.1 to 10^{-4} mtorr). A diagram of the sputter coating process is shown in Fig. 1. The target (also called a cathode) is connected to a negative voltage supply, and the substrate generally faces the target. A glow discharge is initiated after an inert gas (usually argon gas) is introduced into the evacuated chamber. Typical working pressure of the argon is in the range of 3 to 20 Pa (20 to 150 mtorr). The sputter target erosion rate, *R,* in Å/min, is given by:

$$R = 62.3 \frac{JSM_A}{\rho} \qquad \textbf{(Eq 1)}$$

where *J* is the ion current density in mA/cm^2; *S* is the sputtering yield in atoms/ion; M_A is the atomic weight in grams; and ρ is the density of the target material in g/cm^3. Sputtering yield, *S,* assuming perpendicular ion incidence onto a target consisting of a random array of atoms, can be expressed as:

$$S = \text{constant} \cdot \frac{M_i\, M_t}{(M_i + M_t)} \cdot \frac{E_i}{U} \qquad \textbf{(Eq 2)}$$

where M_i is the mass of the incident atom, M_t is the mass of the target atom, E_i is the kinetic energy of the incident ion, and *U* is the heat of sublimation of the target material.

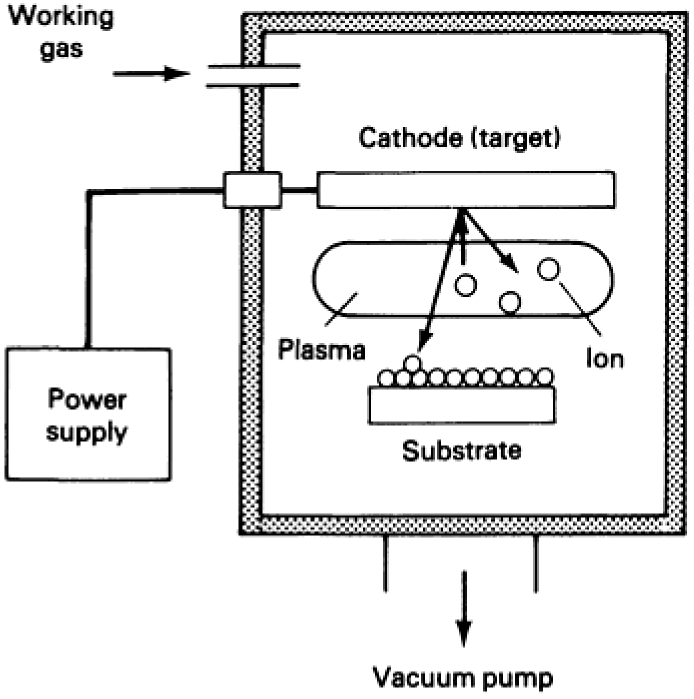

Fig. 1 Schematic showing primary components of a sputter deposition process system

Planar diode glow discharge deposition is the simplest sputtering system. This configuration consists of the cathode (the target) and anode facing each other. The substrates are placed on the anode. The target (which is usually water cooled) performs two functions during the process: one as the source of coating material, and the other as the electrode sustaining the glow discharge. The distance between the cathode and anode is usually about 50 to 100 mm (2 to 4 in.).

The discharge current increases with the applied voltage, thus increasing the sputtering rate. However, the discharge current does not increase linearly with the applied voltage as the voltage increases above 1.6×10^{-17} J (100 eV) because the ionization cross section decreases with increasing electron energy. The sputtering rate can be increased if the working gas pressure increases at a given voltage due to an increase in ion collection by the cathode (Ref 2). However, the deposition rate starts decreasing at high gas pressures due to gas scattering of the sputtered atoms.

The deposition rate is mainly determined by the power density at the target surface, the size of the erosion area, the source-to-substrate distance, the source material, and the working gas pressure. Some of these factors, such as pressure and power density, are interrelated. Therefore, the optimum operating condition is obtained by controlling the parameters to get the maximum power flux that can be applied to the target without causing cracking, sublimation, or melting. The maximum power limit can be increased if the cooling rate of the target is increased by designing the coolant flow channels properly and improving the thermal conductance between the target and the target backing plate.

Even though planar diode glow discharge sputter deposition techniques are widely used due to their simplicity and the relative ease of fabrication of targets for a wide range of materials, they have several disadvantages. Among the disadvantages of this deposition technique are the low deposition rate, the substrate heating due to the bombardment of high-energy particles, and the relatively small deposition surface areas.

Magnetron Deposition. By employing magnetic fields in the diode sputtering process, the ionization efficiency can be greatly increased. In the conventional planar diode process, ions are generated relatively far from the target and the probability that ions will lose their energy to the chamber walls is great. Furthermore, the number of primary electrons hitting the anode at high energies without experiencing collisions is increased as the pressure decreases, thus reducing ionization efficiency. These electron losses are not offset by impact-induced secondary emission. Therefore, ionization efficiencies are low and the discharge cannot be sustained in planar diodes at pressures <1.3 Pa (<10 mtorr).

In the magnetron sputter deposition process, an applied magnetic field parallel to the cathode surface forms electron traps and restricts the primary electron motion to the vicinity of the cathode. The magnetic field strength is in the range of a few hundred gauss: therefore, it can influence the plasma electrons but not the ions. The electrons trapped on a given field line can advance across the magnetic field to an anode or walls by making collisions (mostly with gas atoms). Therefore, their chances of being lost to the walls or anode without collisions are very small. Because of the higher efficiency of this ionization mechanism, the process can be operated at pressures of ~130 mPa (~1 mtorr) with high current densities at low voltages, thus providing high sputtering rates.

There are several configurations of magnetron sputter deposition technologies. Figure 2 shows key components of the cylindrical magnetron, the planar magnetron, the S-gun magnetron, and the unbalanced magnetron.

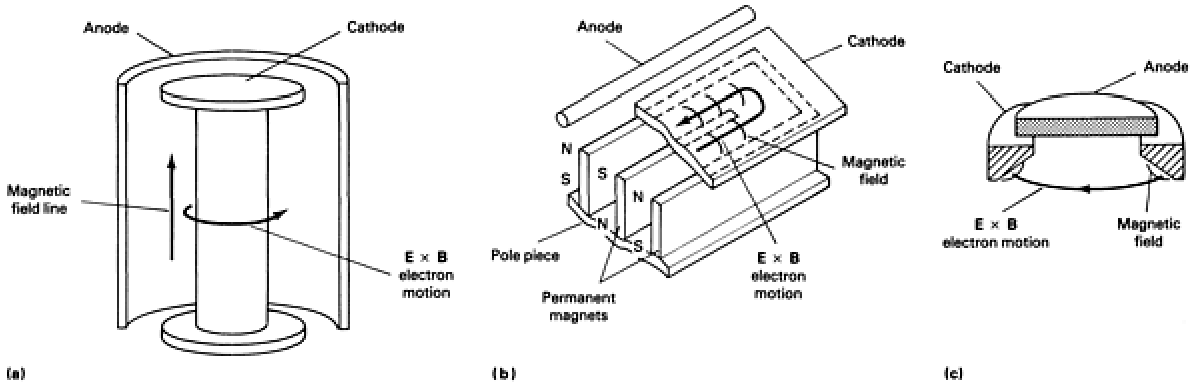

Fig. 2 Magnetron sputter deposition process units that use a variety of sources to supply the magnetic field. (a) Cylindrical magnetron source. (b) Planar magnetron source. (c) S-gun magnetron source

Cylindrical Magnetron. The cylindrical magnetron technique is very useful for preparing uniform coatings over large areas, because it employs long cathodes. Furthermore, the cylindrical-hollow magnetron technique is effective for coating objects with complex shapes. The cylindrical-post magnetron can be used to avoid substrate bombardment by energetic particles, thus preventing heating of the substrate.

Planar Magnetron. Metallic films and dielectric films can be deposited with high deposition rates using planar magnetron sputtering (as compared with those that can be achieved with diode sputtering.

S-Gun Magnetron. To deposit films on thermally sensitive substrate (such as electronic devices), the S-gun magnetron can be used because this technique allows good isolation of the substrate from the glow discharge plasma.

Unbalanced Magnetron. A very recent development is the unbalanced magnetron, in which some of the electrons from the target undergo collisions with gas atoms and form a plasma around the substrate from which ions are attracted to the substrate and bombard the growing film to produce changes in the structure and properties of the deposited film. In the normal balanced magnetron, the ion flux at the substrate is limited.

Magnetron Limitations. Even though the magnetron sputtering techniques have the advantages of high sputtering rates and low bombardment rates of energetic particles onto the substrate, the utilization of these techniques is impeded by the limitations in the choice of target materials and by the difficulties in fabricating the target. For example, if ferromagnetic materials are used as the sputtering target, they should be thin enough to ensure that the material is saturated by the magnetic field. Because high power is localized in a selected area in the magnetron sputtering process, targets should be prepared without voids or bubbles to avoid local melting and spitting.

Radio Frequency Deposition. The development of the radio frequency (rf) sputter deposition technique made it possible to deposit films from nonconducting sputtering targets, which cannot be sputtered by the direct current (dc) methods because of the charge accumulation on the target surface.

Most ions are almost immobile relative to electrons, which can follow the temporal variations in the applied potential at the typical rf frequencies used for sputtering (5 to 30 MHz). When the electrode is coupled to an rf generator, a negative

voltage is developed on the electrode due to the difference in mobility between the electrons and the ions. Because the insulating target electrode simulates a capacitor in the electrical circuit, there should be no dc component to the current flow. Therefore, the voltage on the electrode surface is required to be self-biased negatively to compensate for the difference in mobility of electrons and ions and to satisfy the condition of net zero current (averaged over each cycle). The magnitude of the resulting negative bias is almost the same as the zero-to-peak voltage of the rf signal. The period for the electrode to act as an anode is very short, and the electrode mostly acts as a cathode during the rf cycle. Therefore, the target can be expected to be sputtered as in the dc case. Significant numbers of ions are not accumulated on the target surface while the electrode acts as a cathode because of the high frequency employed in rf sputtering (normally 13.56 MHz).

Deposition can be performed at considerably lower pressures (typically, 0.7 to 2.0 Pa, or 5 to 15 mtorr) in rf sputtering as compared to the planar dc discharge. This is possible because electrons oscillating at high frequency can obtain sufficient energy to cause ionizing collisions and the number of electrons lost (without making collisions) can be reduced.

Radio frequency sputtering is widely used to deposit various kinds of materials (for example, conducting, semiconducting, and insulating coatings) despite the complexity of the rf power source. This technique can also be applied to magnetron sputtering sources.

Ion Beam Deposition. A relatively recent development called ion beam sputtering (Fig. 3) provides:

- Excellent adhesion
- A high-purity deposit resulting from the use of low operational pressures (~13 mPa, or 0.1 mtorr)
- Very low substrate hearing effects because the substrate is not in contact with the plasma

In this technique, an ion beam of high energy (hundreds to thousands of electron volts) extracted from the ion source is directed at a sputtering target of the desired material. An inert or reactive gas is used for the ion beam source. The substrate is suitably located to collect the sputtered species from the sputtering target (Fig. 3). Two primary ion sources are used in practical thin-film deposition: (1) the Kaufman source and (2) the duoplasmatron. No further discussion of these sources will be presented in this article; additional information is available in the book by Wilson and Brewer (Ref 3).

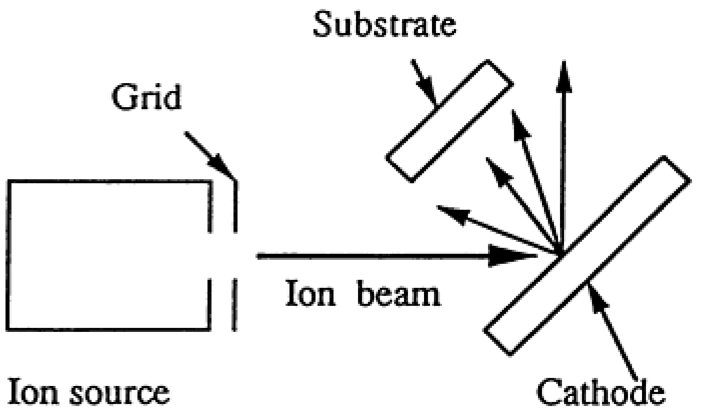

Fig. 3 Key components of an ion beam sputter deposition apparatus

Because the substrate can be isolated from the plasma generation source, ion beam deposition permits independent control over the substrate temperature, gas pressure, and the type of particle bombardment of the growing film. In addition, it is possible to control the energy and the target current density independently in this technique, whereas it can be done only by varying the working gas pressure in conventional glow discharge sputtering technology. The new unbalanced magnetron sputtering systems can also independently vary the ion flux and energy.

In general, the deposition rate in ion beam sputtering (50 nm/min, or 500 Å/min) is lower than that in conventional sputtering. The reason for this low rate is mainly due to the low beam current in the conventional (dual-grid) ion beam sputtering system. This low beam current can be greatly increased by using a single-grid system. Nishimura *et al.* (Ref 4) obtained a very high deposition rate (>90 nm/min, or 900 Å/min, for selected materials such as aluminum, copper, and so on) using single-grid ion beam sputtering. A small coverage of deposition area due to the small ion beam size (~10 mm, or 0.4 in.) is another drawback of the ion beam sputtering. The beam size can be increased to ~100 mm (~4 in.) by adaptation of space-type ion engine technology.

Evaporation Deposition

In evaporation processes, vapors are produced from a material located in a source that is heated by various methods (Fig. 4). The process uses an evaporation source to vaporize the desired material; the substrates are located at an appropriate distance facing the evaporation source. Resistance, induction, arc, electron beam, or lasers are the possible heat sources for evaporation. The substrate can be heated and/or biased to the desired potential using a dc/rf power supply. Evaporation is carried out in vacuum in a pressure range of 1.3×10^{-3} to 1.3×10^{-8} Pa (10^{-5} to 10^{-10} torr). In this pressure range, the mean free path (MFP) is very large (5 to 10^5 m, or 16 to 3×10^5 ft) as compared to the source-to-substrate distance. Hence, the evaporated atoms essentially undergo a collisionless line of sight transport prior to condensation on the substrate, leading to thickness buildup directly above the source that decreases steeply away from it. Planetary substrate holders are therefore used in some cases to even out the vapor flux on multiple substrates. In some cases, an appropriate gas such as argon at pressures of 0.7 to 30 Pa (5 to 200 mtorr) is introduced into the chamber to reduce the mean free path so that vapor species undergo multiple collisions during transport from the source to substrate, thus producing reasonably uniform thickness coatings on the substrate. This technique is called gas scattering evaporation or pressure plating (Ref 5).

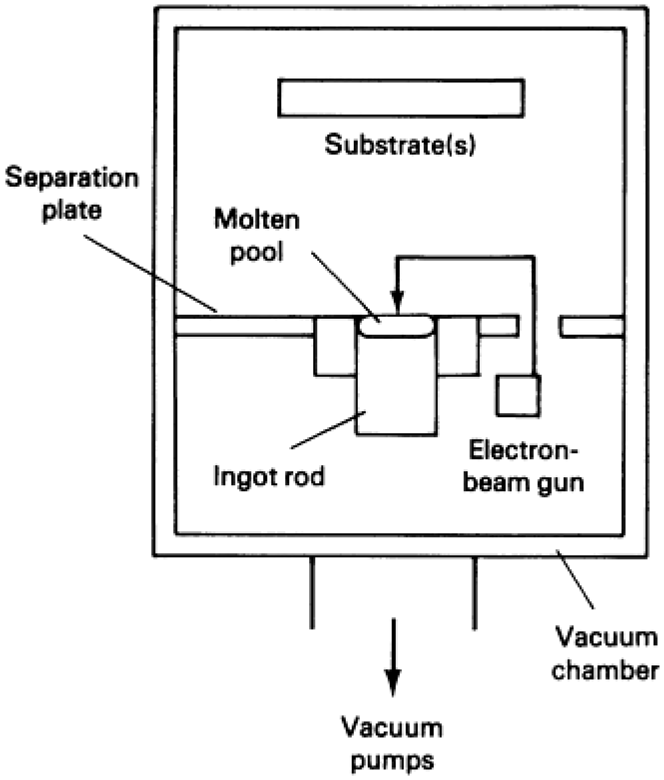

Fig. 4 Typical evaporation deposition process apparatus incorporating an electron beam as a heat source for evaporation

The transition of solids or liquids into the vapor phase is an atomistic phenomenon. It is based on thermodynamics and results in an understanding of evaporation rates, source-container reactions, and the accompanying effect of impurity introduction into the vapor state, changes in composition during alloy evaporation, and stability of compounds. An excellent detailed treatment of the thermodynamic and kinetic bases of evaporation processes is given by Glang (Ref 6).

The rate of evaporation is given by the well-known Hertz-Knudsen equation,

$$dN_e/A_e dt = \alpha_v (2\pi mkT)^{-1/2}(p^* - p) \qquad \textbf{(Eq 3)}$$

where α_v is the evaporation coefficient; $dN_e/A_e dt$ is the number of molecules evaporating from a surface area, A_e in time, dt; p^* is the equilibrium vapor pressure at the evaporant surface; p is the hydrostatic pressure acting on the surface; m is the molecular weight; k is Boltzmann's constant; and T is the absolute temperature. Evaporation coefficient, α_v, is very dependent on the cleanliness of the evaporant surface and can range from very low values for dirty surfaces to unity for clean surfaces.

For reasonable deposition rates (100 to 1000 nm/min, or 1000 to 10^5 Å/min) at a source-to-substrate distance of 200 mm (8 in.), the vapor pressure should be about 1.3 Pa (10^{-2} torr). The source temperature should be adjusted to give this value of the vapor pressure.

The directionality of evaporating molecules from an evaporation source is given by the cosine law. Holland (Ref 7) and others (Ref 8) have thoroughly discussed the theoretical distribution of vapor from a point, a wire, a small surface, an extended tip, and cylindrical and ring types of sources. For the ideal case of deposition from a clean, uniformly emitting point source onto a plane receiver, the rate of deposition varies as (cos θ)r^2 (Knudsen's cosine law), where r is the radial distance of the receiver from the source and $\theta$is the angle between the radial vector and the normal to the receiver direction.

PVD Techniques for Deposition of Metals, Alloys, and Compounds

The great versatility of the PVD processes is their ability to deposit a very large number of materials (for example, metals, alloys, semiconductors, superconductors, and polymers) and to fabricate composites of various types (for example, particulate, fibrous, or laminate).

Single-Element Specie Deposition

Single-element specie deposition can be carried out by evaporation or sputter deposition processes. The deposition rate depends on the process and the process parameters.

Alloy Deposition

Alloys consist of two or more components that have different vapor pressures and, hence, different evaporation rates. As a result, the composition of the vapor phase and the deposit are constantly varying. The following solutions have been used to obtain alloy films with stoichiometry close to the source composition by evaporation-based or sputter-based techniques.

- **Coevaporation or Cosputtering Using Multiple Sources.** This technique involves simulneous coevaporation of the constitutive elements of the alloy. The composition of the deposited film is controlled by adjusting the evaporation/sputtering rate of the respective elements. In elaborate systems, separate deposition rate monitors are used with appropriate feedback networks to control the deposition rate from each individual source independently. Near-stoichiometric films of many binary alloys have been successfully deposited using this technique. Dispersion-strengthened alloys such as Ni-ThO_2 have also been successfully deposited by this technique
- **Evaporation from a Single Source.** This technique involves evaporation of an alloy using a rod-fed electron beam source. Evaporation operates under steady-state conditions where the composition and volume of the liquid pool on the top of a solid rod are kept constant (Fig. 5). A detailed description of the process is given in Ref 9
- **Flash Evaporation.** In this process, pellets of the alloy are dropped onto a very hot strip and are vaporized completely, thus maintaining the composition of the alloy in the deposit. This technique works very well for elements with high vapor pressures
- **Sputter deposition from an alloy target**
- **Sputter deposition from a segmented target** where the segments consist of each of the two

components of the alloy and the ratio of the target sample area of each element is inversely proportional to the sputtering yields
- **Laser ablation from an alloy target**

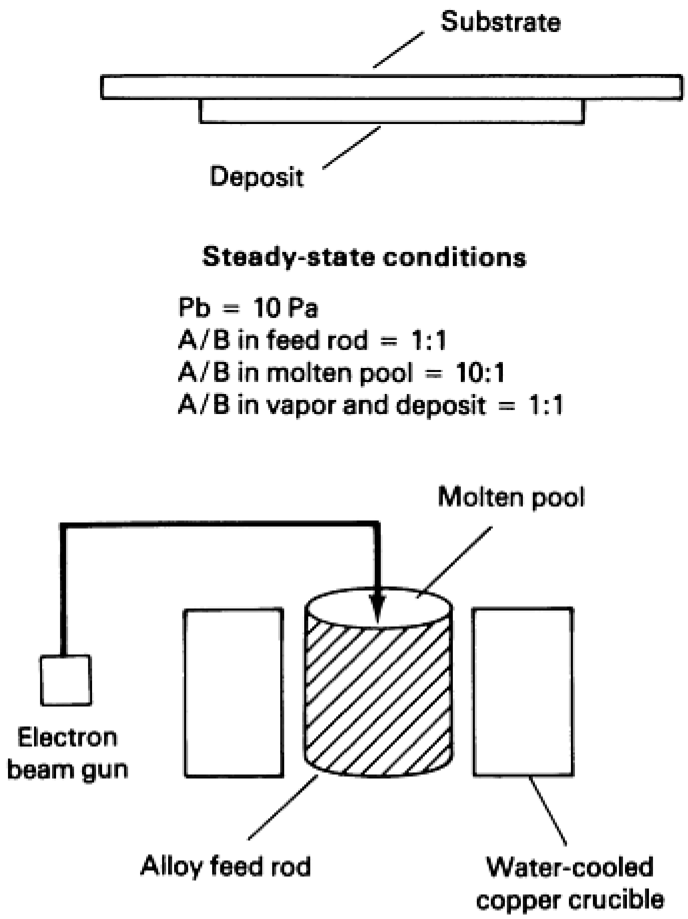

Fig. 5 Schematic showing direct evaporation of an alloy from a single-rod-fed electron beam source. Steady-state conditions: Vapor pressures, P^0_{B} = 10 P^0_{A}; in feed rod composition A_1B_1; molten pool composition $A_{10}B_1$; vapor and deposit composition A_1B_1

Deposition of Compounds

Deposition of compounds can be performed in two ways:

1. *Direct evaporation* using conventional heating methods or laser ablation, where the composition of the evaporant is the same as that of the compound that is to be deposited
2. *Reactive evaporation*, where the elements of the compound are evaporated and react with the gas to form the compound

Plasma-assisted reactive evaporation processes are often used because they activate the reactions leading to compound formation. Reactive evaporation and plasma-assisted reactive evaporation are discussed in the section "Reactive Evaporation Process" in this article.

Direct Evaporation. When a compound is heated, evaporation can occur with or without dissociation of the compound into fragments. A small number of compounds are evaporated without dissociation (for example, SiO_2, MgF_2, B_2O_3, GaF_2, and other Group IV divalent oxides).

Conventional Heating Methods. In the more general case, when a compound is evaporated, the material is not transformed to the vapor state as compound molecules but as fragments thereof. Subsequently, the fragments have to recombine on the substrate to reconstitute the compound. Therefore, the stoichiometry (anion-to-cation ratio) of the deposit depends on factors such as:

- Vaporization rate
- Ratios of the various molecular fragments in the vapor
- Impingement of other gases present in the environment on the film
- Surface mobility of the fragments (which in turn depends on their kinetic energy and substrate temperature) on the substrate
- Mean residence time of the fragments on the substrate
- Reaction rate of the fragments on the substrate to reconstitute the compound
- Impurities present on the substrate

For example, it was found that direct evaporation of Al_2O_3 resulted in a deposit that was deficient in oxygen. In another example, the deposit from direct evaporation of TiB_2 contained both the monoboride and diboride phases (Ref 10).

Laser ablation deposition techniques have attracted great interest in recent years for the synthesis of semiconducting and insulating thin films. Very recently, these techniques have been applied successfully for the deposition of high-critical-temperature (high-T_c) superconducting films (Ref 11, 12).

In the laser ablation technique, material is vaporized and ejected from the surface of a target as it is irradiated by a laser beam. Films are formed by condensing material ablated from the target onto a solid substrate. Absorption characteristics of the material to be evaporated determine the laser wavelength to be used. To obtain the high-power density required in many cases, pulsed laser beams are generally employed. Pulse width, repetition rate, and pulse intensity are selected for specific applications.

Although laser ablation is an attractive approach for the synthesis of high-purity metal, alloy, and compound films, it suffers from the following limitations:

- Complex transmitting and focusing systems need to be employed to direct the beam from the laser located outside the vacuum chamber onto the evaporant placed inside the system. This involves special designs and increases the cost of the setup. In addition, a window material that efficiently transmits the wavelength band of the laser must be found and mounted in such a way that it is not rapidly covered up by the evaporant flux
- It is not always possible to find a laser with a wavelength that is compatible with the absorption characteristics of the material to be evaporated
- Energy conversion efficiency is very low
- The size of the deposited film is small (10 to 20 mm, or 0.4 to 0.8 in., diameter), resulting from the small size of the laser impact spot

Reactive PVD processes are those in which at least one of the elements of the coating is introduced in the gas phase. Various compounds have been synthesized from metal targets with reactive gases:

- Oxides with air, O_2, or H_2O
- Nitrides with N_2 or NH_3
- Oxynitrides with $O_2 + N_2$
- Sulfides with H_2S

There are several advantages to these processes. For example, various kinds of compounds can be prepared using relatively easy-to-fabricate metallic targets, insulating compound films can be prepared using direct current (dc) power supplies (reactive sputtering), and graded composition films can be formed.

Reactive Sputtering (RS). In the RS process, sputter deposition is performed in the presence of reactive species in the gas phase. Reactions can occur on the cathode surface, at the substrate, and in the gas phase. However, reactions in the vapor phase are precluded by considerations of momentum and energy conservation unless the process is performed at high pressures to allow multiple-body collisions in the gas phase.

The target is a nominally pure metal. The compound film is synthesized by sputtering in a pure reactive gas or mixture of inert gas and reactive gas. Usually, the inert-reactive gas mixture is preferred because of sputtering rate considerations. A compound target also can be used in the RS technique. In this case, the target is chemically decomposed by inert gas ion bombardment. It is usually necessary to add the reactive gas to compensate for the loss of the reactive component by dissociation.

The main problem in reactive sputtering is target poisoning. As the reactive gas partial pressure increases, the rate of compound formation exceeds the removal rate of compounds on the target surface, resulting in a decrease in deposition rate due to the low sputtering yield of the compound formed on the cathode surface and to the fact that compounds have higher secondary electron emission yield than pure metals. The increase in secondary electron emission results in a reduction in both the discharge voltage and ion component in the cathode current at constant voltage. In other words, more of the energy of incoming ions is consumed to produce and accelerate secondary electrons. Various solutions have been found to reduce the effect of target poisoning (Ref 13).

Reactive Evaporation Process. The difficulties involved in direct evaporation processes due to fragmentation of the vaporized compounds are overcome in reactive evaporation, where a metal is evaporated in the presence of the reactive gas. The compound is formed by reaction of the evaporating metal species with the molecules of the reactive gas. Even though this technique has been extensively used to deposit a variety of oxide films for optical applications, it is generally observed that the films are deficient in oxygen. It is also observed in some cases (for example, the synthesis of carbide films) that the deposition rate becomes a limiting factor governing the growth of the films. In such cases, stoichiometric titanium carbide films could be deposited only at very low rates (~0.15 nm/s, or 1.5 Å/s). This deposition rate limitation is due to the reaction kinetics of the compound formation in this process. The presence of a plasma in the activated reactive evaporation (ARE) process influences the reaction kinetics by providing activation energy to the reactive species, thereby making it possible to synthesize compound films at considerably higher rates (Ref 14) and lower temperatures.

Activated Reactive Evaporation. The ARE process generally involves evaporation of a metal or an alloy in the presence of the plasma of a reactive gas (Ref 15, 16). For example, titanium carbide and titanium nitride coatings are deposited with this process by evaporating titanium in the presence of C_2H_2 and N_2 plasmas, respectively. The two basic variants of the ARE process (one version incorporates an electron beam to evaporate the target material, whereas the other version utilizes resistance elements to provide the heat required to evaporate the target material) are shown in Fig. 6. Detailed information on other modifications of the ARE process is available in the article by Bunshah and Deshpandey (Ref 17).

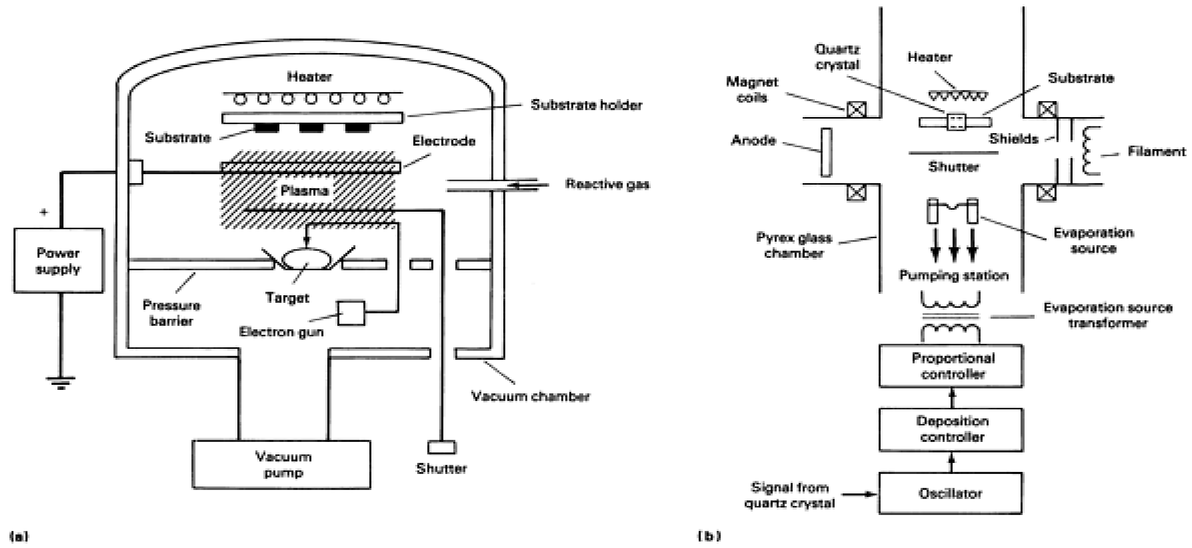

Fig. 6 Activated reactive evaporation (ARE) process equipment incorporating different heat sources to evaporate target materials. (a) Electron beam source. (b) Resistance element heating source

The role of the plasma is two-fold:

1. To enhance the reactions that are necessary for deposition of compound films
2. To modify the growth kinetics and, hence, the structure/morphology of the deposits

Hybrid PVD Processes. Ion plating and reactive ion plating (RIP) are two deposition processes classified as hybrid PVD processes.

Ion plating is a hybrid process (Ref 18) because the coating material is vaporized by thermal energy (that is, evaporation) or momentum transfer (that is, sputtering) or supplied as a vapor (very similar to CVD processes). In this technique, the vaporized (or supplied) coating materials pass through a gaseous glow discharge on their way to the substrate, thus ionizing some typically 1% of the vaporized atoms.

The glow discharge is produced by biasing the substrate to a high negative potential (-2 to -5 kV) and admitting a gas (usually argon) at a pressure of 0.7 to 30 Pa (5 to 200 mtorr) into the chamber (Fig. 7). In this simple mode, which is known as diode ion plating, the substrate is bombarded by high-energy gas ions that sputter off the material present on the surface. This results in a constant cleaning of the substrate (that is, a removal of surface impurities by sputtering), which is desirable for producing better adhesion and lower impurity content. The ion bombardment also causes a modification in the microstructure and residual stress in the deposit. On the other hand, it produces the undesirable effects of decreasing the deposition rate because some of the deposit is sputtered off; it also causes a considerable (and often undesired for microelectronic applications) heating of the substrate by the intense ion bombardment. The latter problem can be alleviated by using the supported discharge ion-plating process, in which the substrate is no longer at the high negative potential because the electrons necessary for supporting the discharge come from an auxiliary heated tungsten filament. The high gas pressure used during deposition causes a reasonably uniform deposition on all surfaces due to gas scattering.

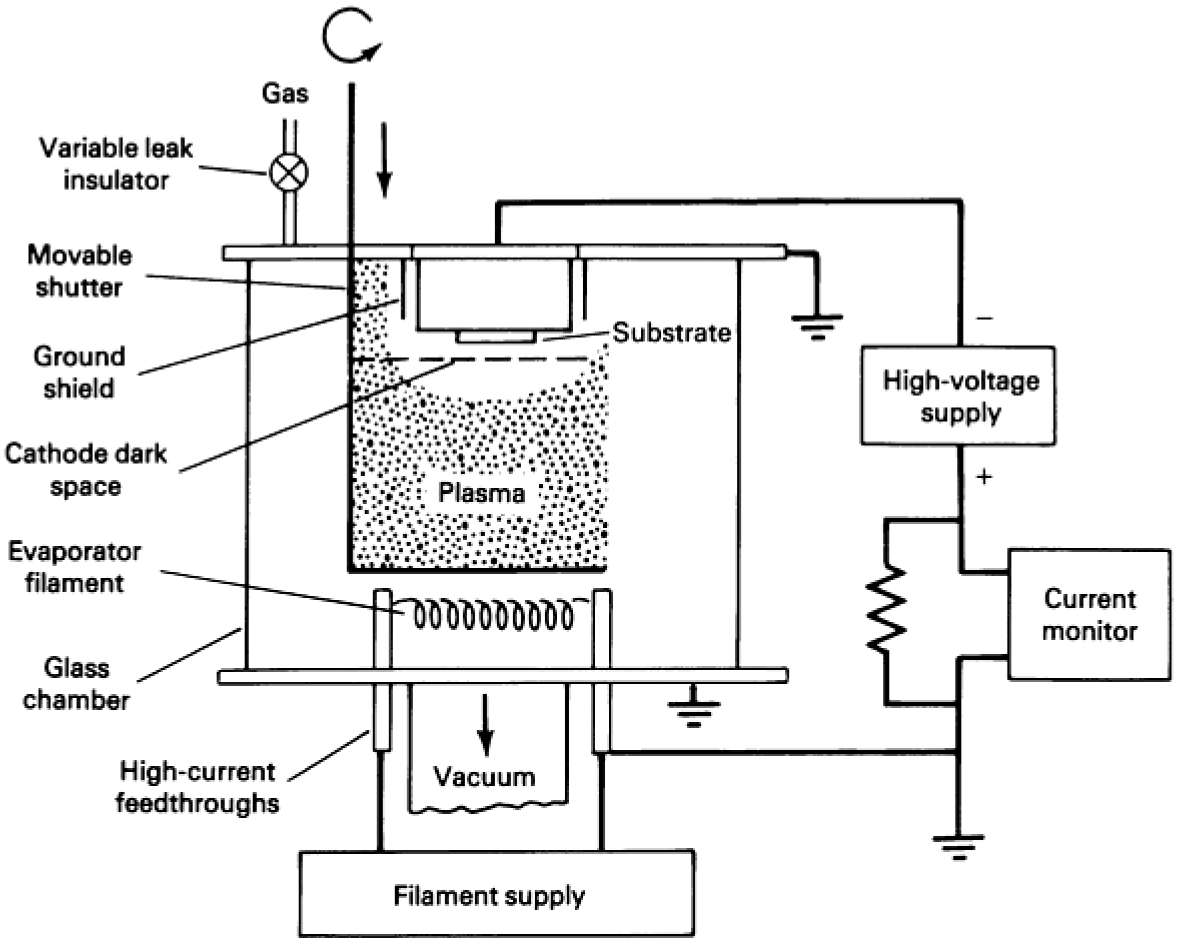

Fig. 7 Typical ion-plating process system that uses a dc diode discharge to ionize the vaporized atoms

Reactive ion plating is very similar to the reactive evaporation process in that the metal atoms and reactive gases, aided by the presence of a plasma, react to form a compound. Because the partial pressure of the gases in reactive ion plating is much higher (>1.3 Pa, or 10^{-2} torr) than in the ARE process (>0.013 Pa, or 10^{-4} torr), the deposits can become porous or sooty. The plasma cannot be supported at lower pressures in the simple diode ion-plating process. Therefore, Kobayashi and Doi (Ref 19) introduced an auxiliary electrode biased to a positive low voltage (as originally conceived for the ARE process) to initiate and sustain the plasma at lower pressure (~0.13 Pa, or 1 mtorr) (Fig. 8). This is no different from the ARE process with a negative bias on the substrate reported much earlier by Bunshah (Ref 20) and designated by him as the biased ARE (BARE) process.

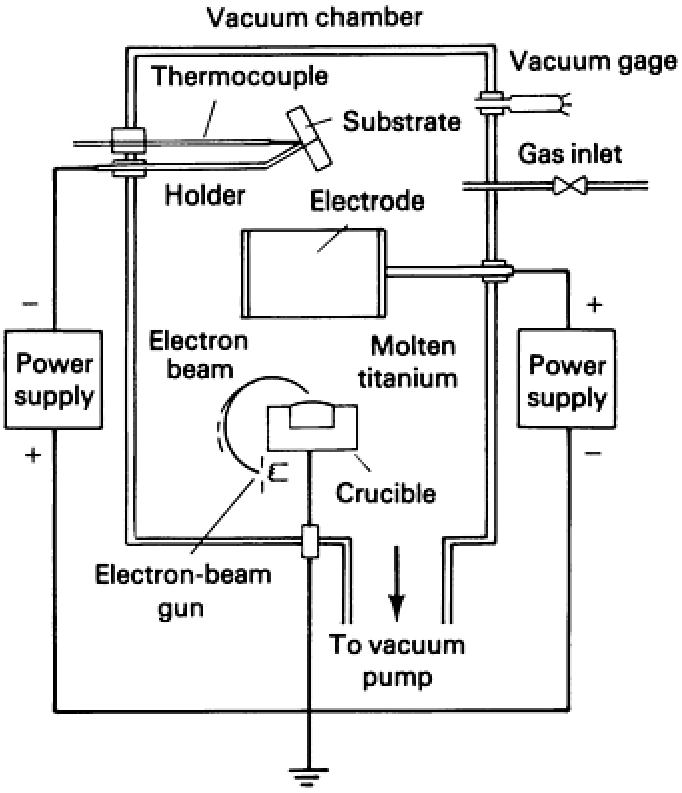

Fig. 8 Schematic of a reactive ion plating (RIP) system that incorporates an auxiliary electrode biased to a positive low voltage to generate plasma at relatively low pressure

Another variation of reactive ion plating using a triode configuration (Ref 21) involves injection of electrons into the reaction zone between the electron-beam-heated evaporation source and the negatively biased substrate from a heated tungsten filament mounted transversely to the metal vapor path. These low-energy electrons are pulled across the reaction zone by a positively biased anode located opposite the cathode. The arrangement is very similar to that shown in Fig. 8 except that it uses an electron-beam-heated (EB-heated) evaporation source; it is also very similar to triode sputtering. The EB-heated evaporation source adds versatility as well as complexity to the process through the addition of another process variable. Murayama (Ref 22) used an EB-heated source with a negatively biased substrate and rf activation of the reactants by means of a coil electrode of aluminum wire in the reaction zone to deposit oxide and nitride films.

Chemical Vapor Deposition Processes

Chemical vapor deposition processes are widely used in industry because of their versatility for depositing a very large variety of elements and compounds covering a wide range of materials from amorphous deposits to epitaxial layers having a high degree of perfection and purity.

Chemical vapor deposition can be defined as a process in which the gaseous chemical reactants are transported to the reaction chamber, activated thermally (conventional CVD) or by other means (plasma-assisted CVD or laser-induced CVD) in the vicinity of the substrate, and made to react to form a solid deposit on the substrate surface. It is possible to deposit films of uniform thickness and low porosity even on substrates of complicated shape with this process. If a metal-organic or organic-metallic precursor species is used in a CVD process, the process is designated MOCVD or OMCVD.

A major area for utility of chemical vapor deposition is in microelectronics applications (for example, gate-insulating layers, passivation layers, oxidation barriers, doped epitaxial layers of silicon, polycrystalline silicon layers, and so on). CVD techniques are also extensively employed to deposit protective coatings for a variety of operating environments where protection is required against the effects of wear, erosion, and high-temperature oxidation.

Conventional CVD (Thermal CVD) Processes

In conventional CVD (CCVD), the gaseous reactants are activated thermally in the vicinity of the heated substrate and react to form a film on the substrate. This technique is referred to simply as chemical vapor deposition in many cases (Fig. 9).

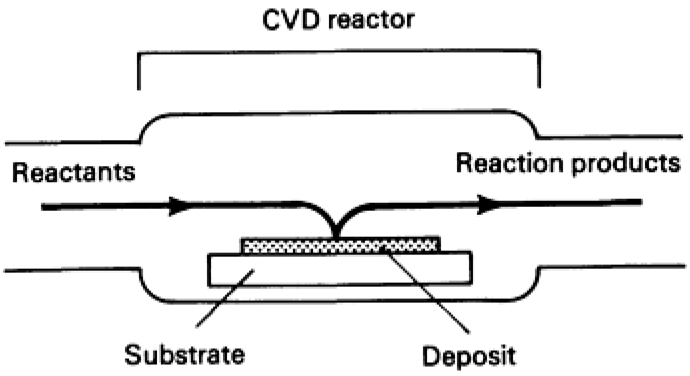

Fig. 9 Key components in a conventional chemical vapor deposition (CCVD) system

Heating sources used in CVD processes include:

- *Hot plate:* The substrate is in direct contact with a hot plate that is either resistively or inductively heated
- *Radiant heat:* The substrate is heated by a thermal radiation technique or optical technique (tungsten filament lamp or laser)
- *Heating of a conductive substrate:* Conductive substrates can be heated resistively or by rf induction

Classification of CVD Reactions. CVD reactions fall into four general categories: (1) thermal decomposition reactions, (2) reduction reactions, (3) displacement reactions, and (4) disproportionation reactions.

Thermal Decomposition Reactions (Pyrolytic Reactions). This type of reaction is characterized by:

$$AX(g) \rightarrow A(s) + X(g) \qquad \textbf{(Eq 4)}$$

where *AX* is a gaseous compound, *A* is a solid material, and *X* is a gaseous reaction product. Some examples of these reactions are:

$$B_2H_6(g) \rightarrow B(s) + 3H_2(g) \qquad \textbf{(Eq 5)}$$

$$SiH_4(g) \rightarrow Si(s) + 2H_2(g) \qquad \textbf{(Eq 6)}$$

$$W(CO)_6(g) \rightarrow W(s) + 6CO(g) \qquad \textbf{(Eq 7)}$$

Reduction Reactions. In these reactions, a gaseous compound is reduced by a reducing agent (usually hydrogen):

$$2AX(g) + H_2(g) \rightarrow 2A(s) + 2HX(g) \qquad \textbf{(Eq 8)}$$

Typical reduction reactions include:

$$2BCl_3(g) + 3H_2(g) \rightarrow 2B(s) + 6HCl(g) \qquad \textbf{(Eq 9)}$$

$$SiCl_4(g) + 2H_2(g) \rightarrow Si(s) + 4HCl(g) \qquad \textbf{(Eq 10)}$$

Displacement Reactions. These reactions are also known as exchange reactions. In the molecule *AX*, *X* is replaced by another element, *B*.

$$AX(g) + B(g) \rightarrow AB(s) + X(g) \qquad \textbf{(Eq 11)}$$

Some representative reactions include:

$$Zn(g) + H_2S(g) \rightarrow ZnS(s) + H_2(g) \qquad \textbf{(Eq 12)}$$

$$SiCl_4(g) + CH_4 \rightarrow SiC(s) + 4HCl(g) \qquad \textbf{(Eq 13)}$$

$$CrCl_2(g) + 2Fe(s) \rightarrow \text{Cr-Fe alloy} + FeCl_2(g) \qquad \textbf{(Eq 14)}$$

Disproportionation Reactions. In these reactions the oxidation number of an element both increases and decreases through the formation of two new species. Some typical examples of disproportionation reactions are:

$$2GeI_2(g) \rightarrow Ge(s) + GeI_4(g) \qquad \textbf{(Eq 15)}$$

$$2TiCl_2(g) \rightarrow Ti(s) + TiCl_4(g) \qquad \textbf{(Eq 16)}$$

Complex CVD Reactions. Several types of reactions can be involved simultaneously in some CVD coating processes. An example of these reactions is:

$$2AlCl_3(g) + 3CO_2(g) + 3H_2(g) \rightarrow Al_2O_3(s) + 3CO_2(g) + 6HCl(g) \qquad \textbf{(Eq 17)}$$

In this reaction, water produced from:

$$CO_2(g) + H_2(g) \rightarrow CO(g) + H_2O(g) \qquad \textbf{(Eq 18)}$$

is used to form Al_2O_3 by the following reaction:

$$2AlCl_3(g) + 3H_2O(g) \rightarrow Al_2O_3(s) + 6HCl(g) \qquad \textbf{(Eq 19)}$$

Rate-Limiting Steps. The sequence of events in a CVD process is as follows (Ref 23):

1. Diffusion of reactants to the surface
2. Adsorption of reactants at the surface
3. Surface events (for example, chemical reaction, surface motion, lattice incorporation, and so on)
4. Desorption of products from the surface
5. Diffusion of products away from the surface

Among these five steps, the slowest one is the rate-determining step.

The rate-limiting step is mainly determined by the process parameters. The most important rate-limiting steps in the CVD process are mass transport control and surface kinetics control. The latter produces uniform deposits on complex-shaped substrates.

Reactors. Two kinds of reactors are used most frequently in the CVD processes: hot-wall reactors (Fig. 10a) and cold-wall reactors (Fig. 10b).

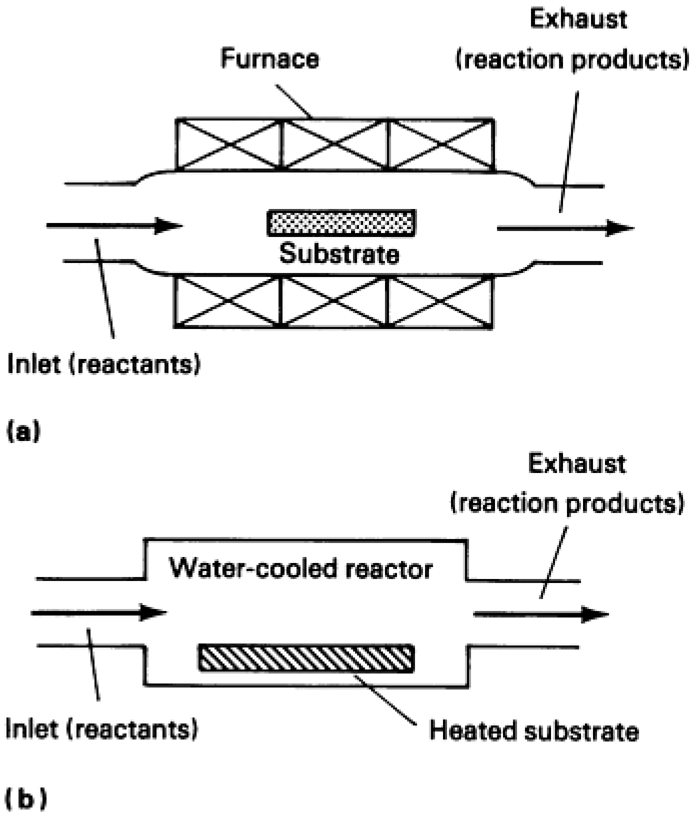

Fig. 10 Two types of chemical vapor deposition (CVD) reactors. (a) Hot-wall reactor. (b) Cold-wall reactor

Hot-Wall Reactors. In the hot-wall reactor, the reactor tube is surrounded by a tube furnace making the temperature of the substrate equal to the temperature of the reactor wall. A large number of substrates can be coated in this type of reactor. A major drawback of this type of reactor is deposition on the reactor wall and possible contamination in the system from chemical reactions between the reactor wall and the vapor due to the high temperature of the reactor wall. Therefore, the hot-wall reactor is ideal for use where the reaction is exothermic because the high wall temperature prevents undesirable deposition on the reactor walls. Groups III-V and II-VI type semiconductors have been successfully prepared in the hot-wall reactor.

Cold-Wall Reactor. In the cold-wall reactor, only the susceptor where the substrates are placed is intentionally heated by rf induction or high-radiation lamps. This type of reactor is predominantly used for the deposition reaction, which is endothermic (for example, silicon deposition from the halides or the hydride). Because the substrates have a higher temperature than the reactor wall, the reaction will proceed most readily on the hot surface of the substrate. In this type of reactor, contamination due to the interaction between the reactor wall of the vapor can be greatly reduced. Very frequently, the walls are water-cooled to further prevent deposition on the wall or reactions between the walls and the vapor.

Low-Pressure Chemical Vapor Deposition

Low-pressure CVD (LPCVD) technology is widely used in the semiconductor industry because it offers several advantages over the conventional atmospheric-pressure CVD technique. By operating at lower pressure to increase diffusivity in the gas phase and increasingly subjecting the system to surface kinetics control, the uniformity of deposition

is enhanced. The mass transfer rate and the surface reaction rate are generally of the same order of magnitude at normal atmosphere pressure (CCVD), while the mass transfer rate is much higher than the surface reaction rate at lower pressure (that is, 70 to 130 Pa, or 0.5 to 1 torr) using LPCVD and thereby the rate-determining step is the surface reaction. The transfer rates of gaseous reactants and reaction products are inversely proportional to pressure. If the pressure is reduced from 1.0×10^5 Pa (760 torr) to 70 to 130 Pa (0.5 to 1 torr), diffusivity increases by a factor of 1000, which is only partially offset by the increase in thickness of the boundary layer (by the square root of pressure) (Ref 24). At this low pressure, mass transfer cannot be the rate-limiting step and the deposition rate is mainly controlled by surface reactions, resulting in uniform film thickness and properties over extended surfaces with better step coverage and conformality, and good structural integrity with fewer pinholes.

Another advantage of low-pressure chemical vapor deposition occurs because the mean free path is very large at lower pressures; therefore, wafers can be stacked on edged instead of lying flat, and thus a large number of wafers can be loaded and deposited in the same run (Fig. 11).

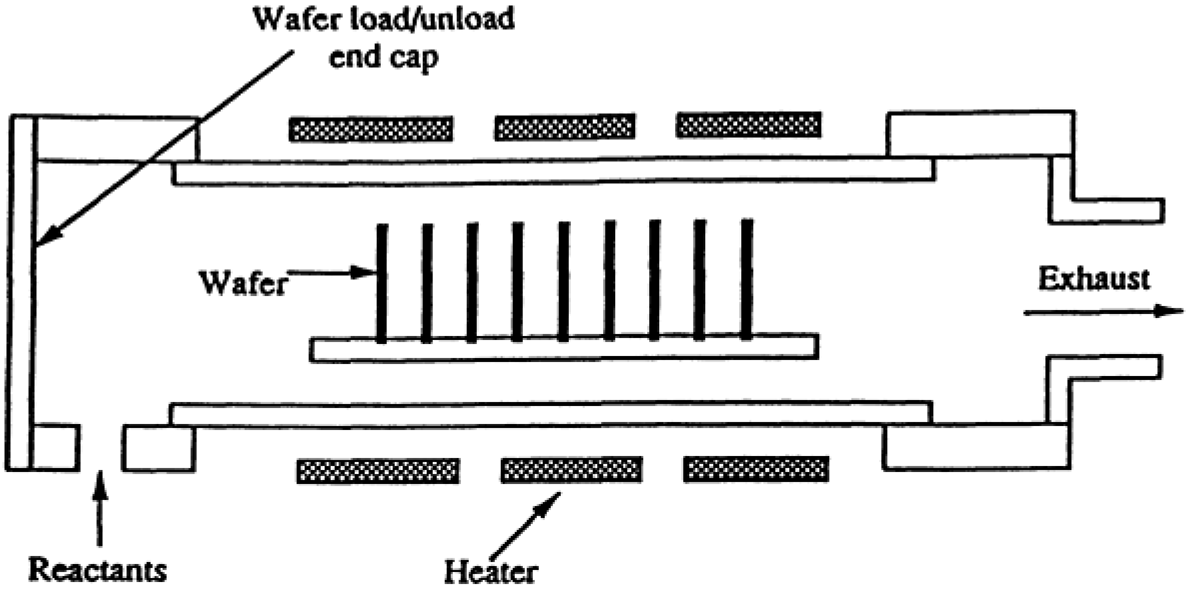

Fig. 11 Typical low-pressure chemical vapor deposition (LPCVD) reactor used in semiconductor industry applications to coat silicon wafers

Polycrystalline silicon films from SiH_4, Si_3N_4 films from SiH_2Cl_2 and NH_3, and SiO_2 films from SiH_2Cl_2 and N_2O have been successfully prepared using this technique (Ref 25, 26).

Plasma-Assisted Chemical Vapor Deposition

Plasma-assisted chemical vapor deposition (PACVD) can be defined as a process in which the constituents of the vapor phase react to form a solid film when assisted by an electric discharge. In the PACVD technique, the gas molecules are mainly dissociated by electron impact to generate very reactive neutral, radical, and ion species. These reactive species arrive on a surface and react with each other via an ionic or free radical mechanism in the film-forming process. Because the gas molecules are activated by the energetic electrons instead of thermal energy, the reaction temperature can easily be reduced. Films can be deposited at temperatures typically <300 °C (<570 °F). Furthermore, the inherent limitations of conventional thermodynamics and of chemical availability in conventional chemical vapor deposition are eliminated in plasma activation (Ref 27) due to the nonequilibrium nature of the glow discharge plasma. Key components of a microwave plasma CVD apparatus are shown in Fig. 12.

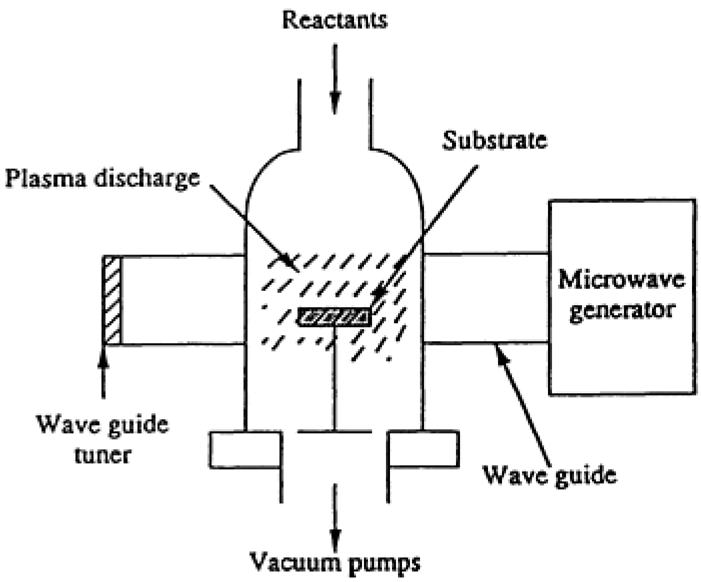

Fig. 12 Schematic showing key components of a microwave plasma chemical vapor deposition apparatus

Neutral radicals are believed to be the major deposition agents among the reactive species generated in the plasma due to the following two effects (Ref 24):

- Dissociation energy is usually lower than the ionization energy for many gas molecules; therefore, the generation rate for radicals is generally greater than that for ions
- Positive ions may drift toward any surface and recombine with electrons, whereas neutral radicals may have more chance to stay in the plasma and have a longer lifetime

The number of neutral radicals is determined by the following parameters:

- Glow discharge power
- Electrode spacing
- Gas collision mean free path
- Ion diffusivity

These variables determine the electron temperature (energy states of the electrons in the plasma) and thereby the radical generation rate. The radical generation rate is roughly proportional to $e^{-(\Delta E)/kT_e}$, where ΔE is the dissociation energy of gas molecules; T_e is the electron temperature; and k is the Boltzmann constant. This relation indicates that the number of gas radicals that have higher dissociation energy will change more with the electron temperature than those of the species with lower dissociation energy (Ref 26). This change in the valued of the radical ratio is the primary factor determining the film stoichiometry.

Ion Bombardment Energy. Even though ions do not contribute greatly to the film-forming process (Ref 27, 28), the ions impinging on the film during growth significantly affect the physical properties of the film (Ref 29). The ionic bombardment energy is determined by several factors (for example, discharge power, gas type and pressure, target bias, and radio frequency). At lower pressure (<7 Pa; or 0.05 torr) and low frequency $\ll$1 MHz), the ions can bombard onto the surface with the full energy available to them because the ions can follow the rf field and do not experience appreciable scattering. The ionic bombardment energy is an average plasma potential as the pressure and the frequency increase.

Substrate Temperature. The substrate temperature still plays an important role in the PACVD process, although the activation energy for the chemical reaction is provided mainly by the glow discharge. During film growth, the absorbed radical has to diffuse to a stable site to become part of the growing film. This radical mobility on the surface of the substrate is strongly affected by substrate temperature. The radicals on the surface obtain more energy and diffuse to the stable site easily at a high substrate temperature to produce a denser film. At low temperatures, however, the diffusion of adatoms (that is, atoms adsorbed on a surface so that they will migrate over the surface) on the surface is extremely retarded and therefore the film has more defects and a lower density. Furthermore, the stoichiometry of the film can be affected by substrate temperature. In the case of PACVD silicon nitride, the content of hydrogen in the grown film can be reduced greatly by increasing the substrate temperature.

Advantages of PACVD over CCVD Processes. There are several advantages of PACVD processes over CCVD processes:

- Ability to deposit films at much lower temperature
- Can be used to prepare the heavily hydrogenated amorphous silicon films for solar cells
- Good adhesion and bond strength of the films to their substrates
- Higher deposition rates than the CCVD technique

Limitations of PACVD Processes. The present limitations of PACVD processes include:

- More numerous defects in the films and a lower density of the film compared to a high-temperature deposited film
- Difficulties in deposition of pure materials
- Extreme difficulty in controlling stoichiometry

Advanced CVD Techniques

The two latest state-of-the-art CVD technologies are known as hot-filament chemical vapor deposition and laser-induced chemical vapor deposition (LCVD).

Hot-Filament CVD. Yasui *et al.* (Ref 30) prepared high-quality silicon nitride films with a low concentration of hydrogen at high deposition rates by the hot-filament CVD technique. In this technique, the hot filament (tungsten filament), which is heated to very high temperatures (for example, 2400 °C, or 4350 °F) is placed close (typically, within 80 mm, or 3.1 in.) to the substrate. Yasui deposited films at a deposition rate that was one order of magnitude higher with a smaller activation energy of the growth rate than that of CCVD technique using the same gases. The same techniques are now used to grow diamond films.

Laser-Induced CVD. Because the substrate is bombarded by charged and energetic particles in addition to high-energy radiation in the PACVD process, this technique can introduce deleterious effects for radiation-sensitive electronic devices. Recently, laser-induced CVD processes have been attracting widespread attention. In the LCVD process, the reaction energy is selectively provided by photons.

There are two types of LCVD processes: pyrolytic LCVD and photolytic LCVD.

Pyrolytic LCVD. In pyrolytic LCVD, polyatomic gas molecules are dissociated near a gas-substrate interface by localized heating of the substrate, which is exposed to the laser beam. This technique is limited by the choice of the laser/source gas/substrate system. The gas vapor sources are required to be relatively transparent at the exciting laser wavelength, and the substrates must be strongly absorbing (Ref 29).

Photolytic LCVD. In photolytic LCVD, a molecule near the substrate is decomposed by means of a photochemical reaction. Specific chemical bonds in polyatomic molecules can be broken selectively through the choice of the laser wavelength (Ref 30). In this technique, photodissociation of the vapor source fixes the maximum allowable wavelength of the laser because only radiation that is absorbed by the reactants can lead to a photochemical reaction. LCVD techniques have been successfully employed to synthesize polycrystalline silicon and germanium (Ref 31), aluminum oxide (Ref 32), and silicon (Ref 33).

Materials Deposited by PVD and CVD Techniques

In addition to the deposition of simple element species (for example, refractory metals by chemical vapor deposition for large-scale integrated circuits in addition to chemical applications, aluminum for metallization and decorative coatings, and so on), a number of more complex materials are deposited using PVD and CVD techniques, particularly the plasma-assisted versions listed in Table 3 (Ref 34).

Table 3 Compounds and synthesized deposition rates obtained with commonly used plasma-assisted deposition processes

Material		Plasma-assisted physical vapor deposition		
Compound	**Examples**	**Activated reactive evaporation, /min**	**Reactive sputtering, /min**	**Plasma-assisted chemical vapor deposition, /min**
Common				
Carbides	TiC, SiC, HfC, ZrC, VC	2000-3000	400-1000	150-400
Nitrides	TiN, HfN, ZrN	2000-3000	300-1000	60-150
Oxides	TiO_2, ZrO_2, Al_2O_3, SiO_2	1000-2000	200-800	200-300
Sulfides	TiS_2, MoS_2, MoS_3	1000-2000	. . .	. . .
Exotic				
Superconducting materials	Nb_3Ge, $CuMo_6S_8$	1000-1500	. . .	. . .
Photovoltaic materials	a-SiH_x, $CuInS_2$, $CuInSe_2$[(a)]	1500-2000	50-200	50-100
Optoelectronic materials	Indium tin oxide, ZnO	500-1000	50-75	50-100
Cubic boron nitride		1000-1500	. . .	. . .
Diamond		1-2[(b)]	. . .	1000-3000[(c)]
a-Carbon		1-2[(b)]	300	200

Wear Applications

This subject is extensively treated in a book by B. Bhusan and B.K. Gupta (Ref 35). Soft coatings are extensively used for lubrication or lowered coefficient of friction. On the other hand, hard coatings are essential for good wear resistance with the accompanying low coefficient of friction. Such coatings are primarily carbides, nitrides, oxides, or borides of simple elements or alloys deposited by PVD and CVD techniques. These include relatively simple compositions such as TiN, TiC, and Al_2O_3; more complex compositions such as (TiAl)N and Ti(C,N); and multilayer coatings, such as TiC/Al_2O_3/TiN. It must be emphasized that the substrate must be hard and must also be resistant to elevated temperatures for many applications of hard coatings. The type of wear (for example, adhesive, fretting, abrasive, impact, chemical, and various combinations thereof) encountered must also be considered. The coating has to be tailored to the specific application. For example, the hardest substance known to man, diamond, is not useful for machining ferrous alloys, titanium alloys, or zirconium alloys, due to the chemical wear that occurs between diamond and these metals at high temperatures. Diamond (carbon) dissolves in these metals at high temperatures. Nevertheless, one of the exciting recent developments in hard coatings is the commercial availability of diamond-coated tools to machine aluminum alloys, plastics, and composites.

It is difficult, if not impossible, to provide general guidelines that relate the coefficient of friction of a material directly to its wear rate. Detailed information on coefficients of friction for a wide range of materials is available in the article "Appendix: Static and Kinetic Friction Coefficients for Selected Materials" in this Volume.

The most prominent application of hard coatings for wear is in the life improvement of cutting tools. The CVD process for deposition of hard coatings was developed in the late 1940s and commercially applied to improve cutting tool life nearly 20 years later. One of the problems that had to be overcome to make CVD processing commercially feasible was

the need to reharden and temper the high-speed steel substrate after the CVD process was carried out at temperatures ranging from 1000 to 1100 °C (1830 to 2010 °F). This spurred the development of a low-temperature high-rate deposition process for hard coatings. Such a process (the ARE process) was developed by Bunshah and Raghuram in 1971 (Ref 16). The application of TiC and TiN coatings onto M42 high-speed steel tools by Bunshah and Shabaik (Ref 36) in 1975 was the first demonstration of large increases in cutting tool life. Bhusan (Ref 35) has compiled a table that summarizes tool wear-life improvement. Table 4 is an adaptation of Bhusan's original table.

Table 4 Improvement in cutting tool wear life obtained by deposition of a hard coating on the tool substrate

Tool substrate	Coating material/ treatment	Deposition method[b]	Coating thickness		Improvement in wear life[b]
			μm	**μin.**	
M-42 high-speed steel	TiC	ARE	5-8	200-320	3-8×
Cemented carbide	TiN, TiC	IP, CVD	5	200	IP Comparable to CVD
M10 high-speed steel[a]	TiC, TiN	ARE	2	80	20×
Cemented carbide	TiN	MS	5	200	Several times
Cemented carbide	TiC, TiN	CVD	8-10	320-400	Several Times
Cemented carbide	HfN, TiC/Al_2O_3, Al_2O_3, TiC/TiN	CVD	. . .	. . .	HfN superior
M7 high-speed steel[a]	TiN	MS	1-2	40-80	50×
Cemented carbide	(Ti, Al)N, TiN/TiC	CVD	. . .	. . .	3× better with (Ti, Al)N
M15 high-speed steel[a]	(Ti, Al)N, TiN	IP	. . .	. . .	3× better with (Ti, Al)N
Cemented carbide	TiN, HfN, ZrN	CVD, IP	8-15	320-600	Hardness of IP, MS, ARE; coatings at room temperature superior to CVD

(a) Twist drill.

(b) ARE, activated reactive evaporation; IP, conventional ion plating; CVD, chemical vapor deposition; MS, magnetron sputtering

Future Outlook

The most promising recent breakthrough in the field of multilayer coating technology appears to be the unbalanced magnetron sputter deposition process. This process should provide the next significant step in the improvement and evolution of state-of-the-art multilayer coating technology.

Ion Implantation

George R. Fenske, Materials and Components Technology Division, Argonne National Laboratory

Introduction

ION IMPLANTATION is one of a number of surface modification processes that is emerging as an economical and viable process for improving the near-surface tribological properties of engineering components. In many engineering situations, material selection is often based on a compromise of bulk mechanical properties and near-surface tribological properties, with neither at their optimum values. As a result, there is considerable interest in fabrication processes, such as ion implantation, that make it possible to retain the bulk properties of a given compound yet still achieve desirable tribological properties in near-surface regions.

Ion implantation is a process by which virtually any element in the periodic chart can be injected into near-surface regions of any solid using a beam of high-velocity ions with energies typically ranging from 10 keV up to several MeV. As the

ions slow down in the material, they are distributed at depths ranging from a few nanometers to several micrometers, depending on the particle energy, angle of incidence, and substrate composition. Depending on the ion type, mass, energy, dose, deposition temperature, and substrate composition, the chemical, electrical, thermal, microstructural, and crystallographic properties of near-surface regions can be significantly altered to improve the friction and wear performance of the component.

Some of the advantages and limitations of ion implantation relative to other surface modification processes are listed in Table 1. For tribological applications, the more significant advantages include the low processing temperatures associated with ion implantation, allowing retention of critical bulk properties such as toughness and hardness. Another advantage is that the dimensions of the treated component are not changed significantly, thereby negating the need for subsequent refinishing steps on components with tight tolerances. Technically, the main disadvantage of ion implantation is that it is a line-of-sight process, making manipulation of components with complex shapes necessary to ensure uniform implantation of critical surfaces. However, it should be noted that recent advances in plasma-source technology have led to a novel ion-implantation process called plasma-source ion implantation that is not limited to line-of-sight implantations from one direction. This process will be discussed later in this article.

Table 1 Advantages and limitations of ion implantation

Advantages	Limitations
Low-temperature process	Shallow penetration depths
Retention of bulk properties	Relatively high capital and operating costs
No significant dimensional changes	Line-of-sight process
Solid solubility limit can be exceeded	Peak concentration limited by sputtering processes
Preparation of alloys independent of thermal diffusion	
Permits fast screening of alloy composition effects	
No sharp interfaces, reducing adhesion problems	
Controllable depth distribution of implanted species	
Clean vacuum process	

Ion implantation is a nonequilibrium process that generates a large number of mobile defects in near-surface regions in addition to deposition of the implanted species. In order to understand how these implanted ions and defects affect the tribological performance of near-surface regions, it is necessary to understand the effect of ion implantation on microstructure and mechanical and chemical properties, as illustrated in Fig. 1. The following sections describe the basic physical phenomena that occur during implantation of energetic ions, how these phenomena affect the properties of the implanted regions, and how these properties influence the tribological performance of near-surface regions. A description of the physical equipment used to implant components, critical implantation parameters, and examples of current commercial applications are also provided.

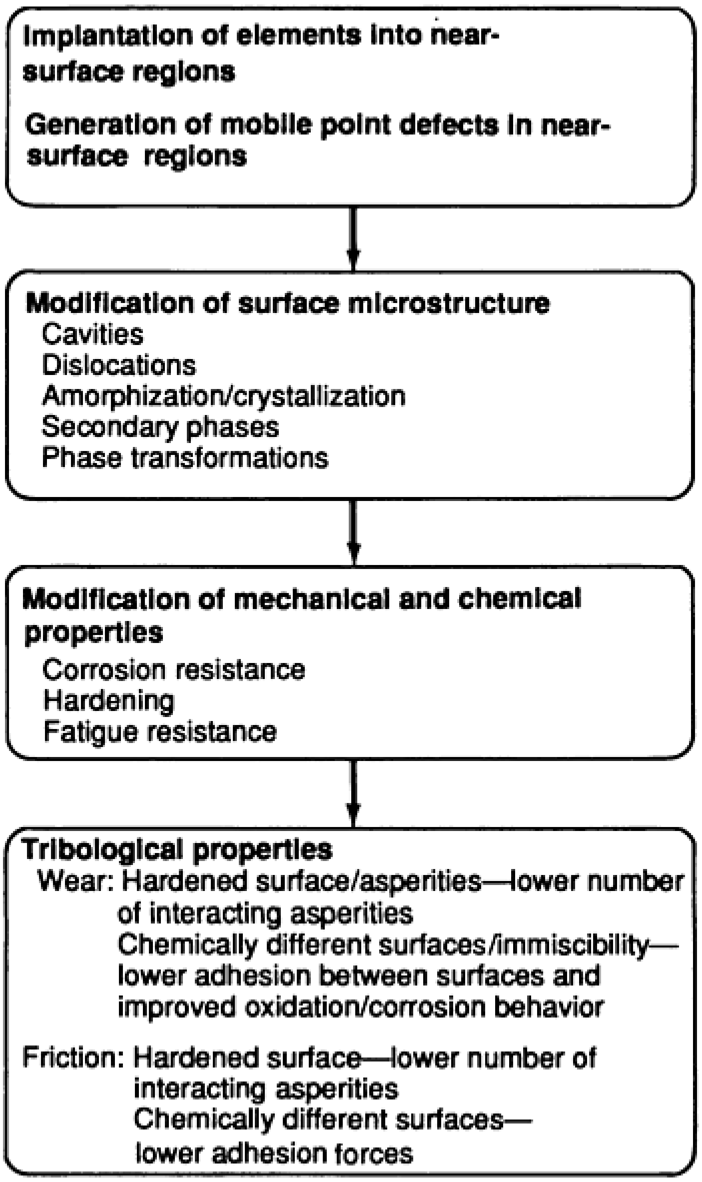

Fig. 1 Flow diagram illustrating mechanisms by which defects produced during ion implantation lead to improved tribological properties

Ion Implantation Processes

Basic Principles. Ion implantation involves creating a charged particle (for example, C^+ or $Ti^{+,2+,3+}$) in an ion source, accelerating the ion to high velocities, and directing a beam of ions onto the substrate, where the ions dissipate their energy and come to rest by colliding with substrate atoms. The resulting defects produced by these collisions, together with the presence of implanted species, interact via a number of processes to produce microstructural changes in the near-surface region that result in altered mechanical and chemical properties.

Figure 2 illustrates phenomena that occur as the ion impinges on the near-surface region of the substrate. As the ions penetrate into the substrate, they undergo numerous collisions with atomic nuclei and electrons, during which energy is transferred to the atoms and electrons. Collisions with atoms in the substrate occur at discrete locations, changing the

direction of the incident ion and resulting in a loss of energy. If the amount of energy transferred to a substrate atom is sufficiently large, the substrate atom is displaced from its original lattice site and is typically called a primary knock-on atom (PKA). Depending on the energy transferred during a collision, a PKA can itself cause displacements of lattice atoms (termed secondary knock-on atoms, or SKAs).

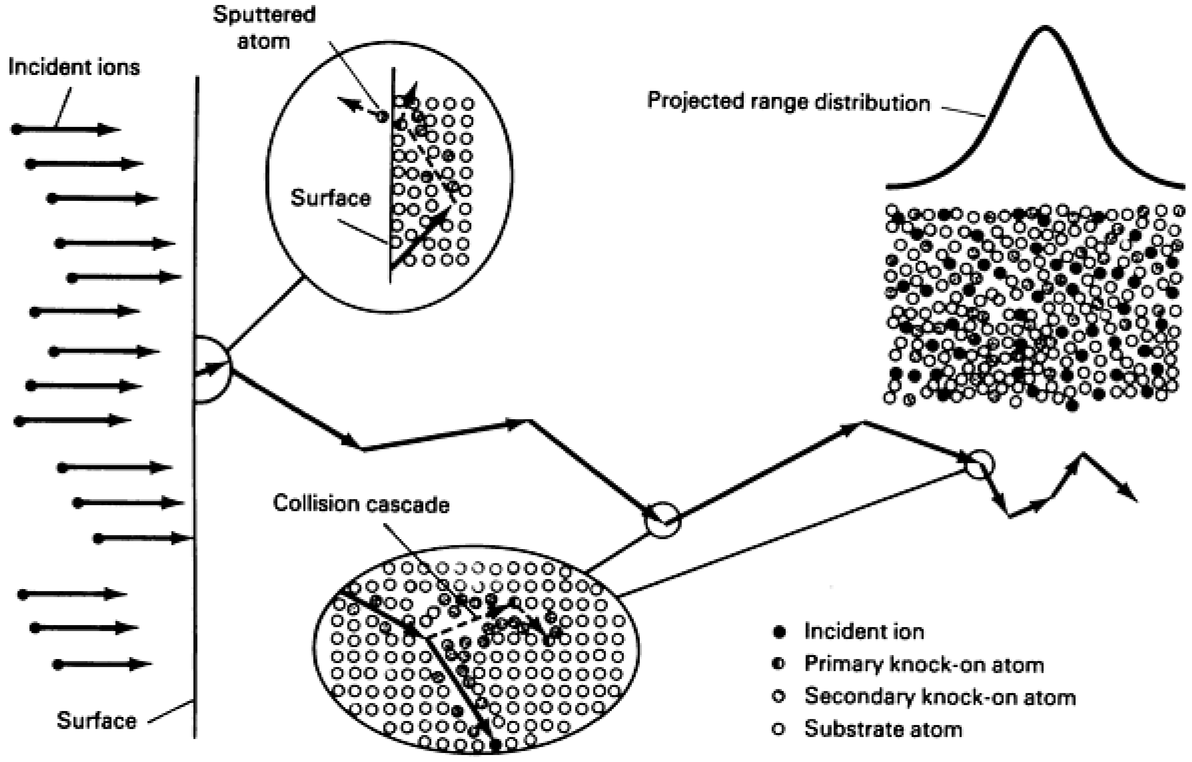

Fig. 2 Schematic of phenomena that occur in near-surface regions during ion implantation

The production of PKAs and SKAs continues until the energy of the respective atoms is below a critical energy where the moving atom/ion can no longer displace another lattice atom (typically on the order of 20 to 50 eV). Because of the scattering kinetics, SKAs are typically produced in a very localized region, called a cascade, around the site where the PKAs are produced. The path of the incident ion will therefore consist of a jagged line along which are distributed a number of cascades of displaced substrate atoms (Fig. 2).

The energy of the incident ion is transferred to both atoms (nuclei) and electrons. The energy transferred to the atoms can be thought of as occurring in the discrete collisions between the incident ion and the PKAs and SKAs. In collisions with electrons, the mass of the electrons is so small compared with that of the moving ions (or PKAs and SKAs) that kinematically very little energy is lost during a single collision. The small mass of the electron also means that the direction of the moving atom is not altered by the collision.

Range and Energy Profiles. Two important parameters that provide valuable insight on the depth of the modified region are the projected range distribution of the implanted ion and the energy deposition profile. The projected range distribution is the probability (per unit depth increment), $P(x)$, that an incident ion will come to rest in the substrate at a distance, x, from the surface of the substrate. The projected range distribution is a function of the atomic number, mass, energy, and angle of incidence of the incident ion and the atomic numbers, masses, and densities of the elements in the substrate. The distribution profiles are usually quoted for ions that have come to rest in the substrate; however, it is possible to calculate distribution functions of ions as they slow down in the substrate--that is, the distribution function of an ion that began with an incident energy, E, and has slowed down to an energy E'. The concentration profile, or atomic density, of the implanted ions, $N(x)$, is the product of the projected range profile and the ion dose, ϕ:

$$N(x) = P(x)\,\phi \qquad \textbf{(Eq 1)}$$

where $N(x)$ is in ions/cm^3, $P(x)$ is in cm^{-1}, and ϕ is in ions/cm^2.

The energy deposition profile represents the energy deposited in the substrate as a function of depth. The energy can represent the energy associated with displacing lattice atoms or the energy associated with ionization processes. A useful parameter that can be derived from the energy deposition (energy associated with displacing atoms) profile is the atomic displacement profile, defined as the average number of times each lattice atom is displaced. Kinchin-Pease (Ref 1) used a simple model to predict the number of atoms displaced by a PKA of energy E as:

$$\nu(E) = \frac{CE}{2E_d} \qquad \textbf{(Eq 2)}$$

where $v(E)$ is the number of displaced lattice atoms due to a PKA of energy E, C is a constant (typically 0.8), and E_d is the energy required to displace a lattice atom (typically 20 to 30 eV). The displacement profile, $G(x)$, is thus the product of the energy deposition function and $C/(2E_d)$:

$$G(x) = \frac{F(x)\,\phi\,C}{2E_d} \qquad \textbf{(Eq 3)}$$

where $G(x)$ is the number of displaced lattice atoms (per unit volume), $F(x)$ is the energy consumed in displacing atoms (eV per unit distance), ϕ is the incident ion flux (number per unit area), and E_d is the displacement energy (eV). Dividing $G(x)$ by the atomic number density (atoms per unit volume) gives the average number of times a lattice atom is displaced, or the displacements per incident atom (commonly called dpa):

$$\mathrm{dpa}(x) = \frac{G(x)}{N} \qquad \textbf{(Eq 4)}$$

where dpa(x) is the average number of times a lattice atom is displaced as a function of depth from the surface and N is the atomic number density of the lattice atoms.

Range and energy (or dpa) profiles can be calculated by analytical treatments or by Monte Carlo simulations of ion-scattering processes. Analytical treatments use spatial moments of the profiles derived from transport theory to reconstruct the depth distributions (Ref 2, 3, 4, 5, 6, 7, 8, 9, 10). Monte Carlo simulations follow the trajectories of a large number of ions as they penetrate and slow down in the lattice (Ref 11, 12). Depth profiles are obtained from Monte Carlo calculations by keeping track of the number of events (for example, lattice atom displacements) that occur in a given depth interval for a large number of incident ions.

Figures 3(a) and (b) show examples of the first and second spatial moments (average projected range and straggling) as functions of the incident-ion energy for nitrogen and titanium ions, respectively, incident on an iron substrate (Ref 11). Note that the range increases with increasing energy; that is, the greater the incident energy, the greater the penetration of the ion into the substrate. Also note that the nitrogen ion penetrates farther than the titanium ion for a given energy (lighter ions penetrate farther than heavy ions). The depth of penetration and hence the approximate depth of the affected zone for 100 keV ions, which are typically used in many tribological implantations, is approximately 40 to 50 nm for titanium and approximately 100 nm for nitrogen in iron.

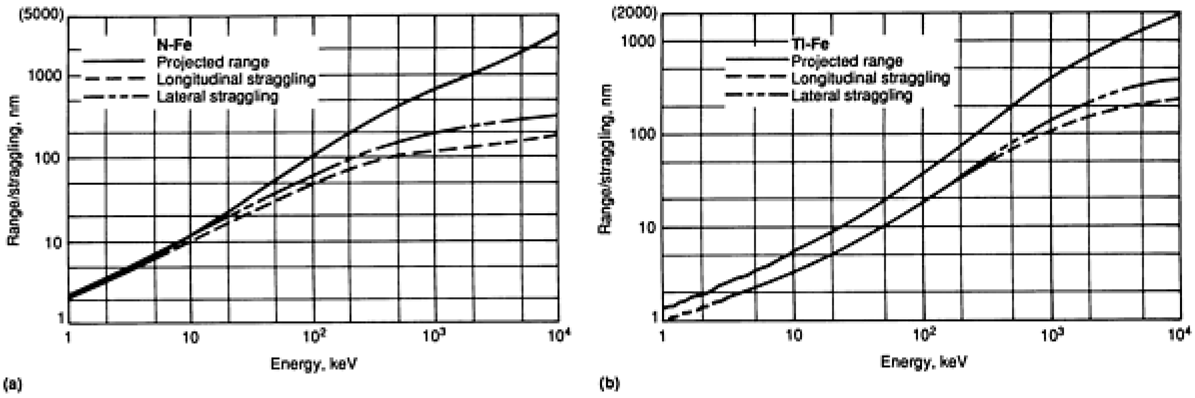

Fig. 3 Examples of projected range and straggling as functions of incident-ion energy. (a) Nitrogen ions incident normal to an iron substrate. (b) Titanium ions incident normal to an iron target. Source: Ref 11

Figures 4(a) and (b) show projected range profiles (solid curves) of 100 keV nitrogen and titanium ions implanted into iron. The profiles were constructed using a Pearson IV distribution function (Ref 13). Also shown are Monte Carlo calculations (based on the trajectories of 10,000 incident ions) of the projected range profiles (denoted by the histograms) and the atomic displacement profiles (dashed curves) (Ref 11). The atomic displacement profiles in Fig. 4 clearly illustrate that 100 keV titanium ions displace considerably more lattice atoms than 100 keV nitrogen ions.

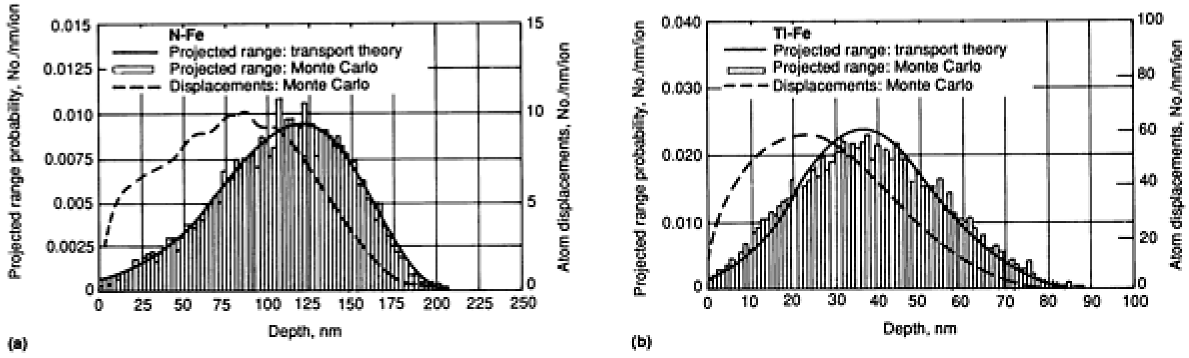

Fig. 4 Damage and projected range distributions of 100 keV nitrogen ions (a) and 100 keV titanium ions (b) incident normal to an iron substrate. Source: Ref 11, 13

Sputtering. Another phenomenon that occurs at the surface, called sputtering, involves the gradual erosion or removal of material from the top surface as it is bombarded by energetic particles. When a collision occurs between an incident ion and a lattice atom or between a PKA and a lattice atom at or near the surface, sufficient momentum can be imparted such that the lattice atom is ejected from the surface. This eventually leads to a gradual erosion or removal of material (both implanted and lattice atoms) from the surface. Subsequent ions are therefore implanted deeper into the surface (measured from the original location of the surface). This has a net effect of limiting the maximum atomic concentration of the ions that can be implanted in near-surface regions.

Figures 5(a) and (b) illustrate the effect of sputtering on the final implant profile for 100 keV nitrogen and titanium implantations, respectively, into an iron substrate (Ref 13). An important parameter in calculating the effect of sputtering on the final implant profile is the rate at which lattice atoms are removed by sputtering. This rate, or sputtering yield, is defined as the number of lattice atoms ejected from the surface per incident ion. The sputtering yield can be calculated analytically (Ref 14), semiempirically (Ref 15), or with Monte Carlo codes (Ref 11), such as those used to generate the projected range and atomic displacement profiles in Fig. 4. The sputtering yield is dependent on the incident ion, energy, substrate composition, and angle of incidence. For the calculations in Fig. 5, the sputtering yields of 100 keV nitrogen and titanium ions incident normal to an iron substrate were calculated to be 0.42 and 4.7 atoms/ion, respectively (Ref 13).

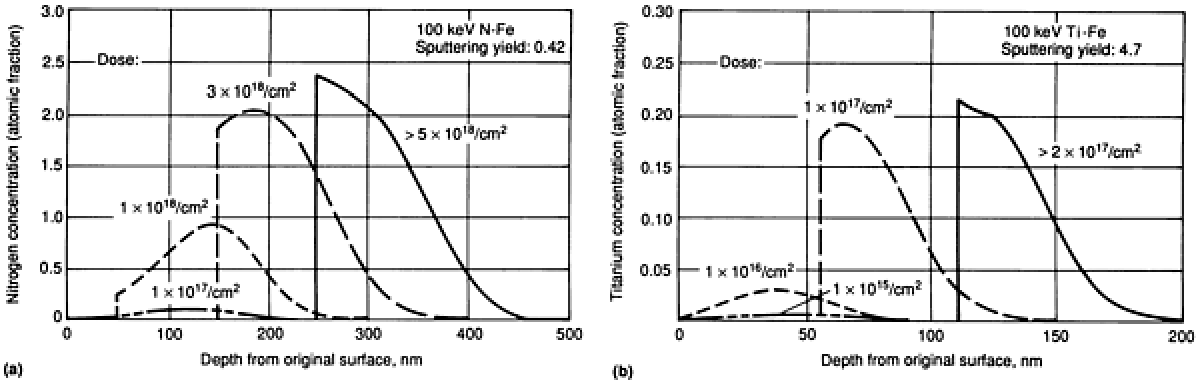

Fig. 5 Concentration profiles of 100 keV nitrogen ions (a) and 100 keV titanium ions (b) implanted into an iron substrate at high doses. Source: Ref 13

At a dose of 1×10^{17} nitrogen ions/cm^2 (Fig. 5a) and a yield of 0.42, approximately 5 nm of material will be removed because of sputtering. As a result, the implant profile is very similar in shape to the projected range profile shown in Fig. 4(a). As the dose is increased, more and more material is sputtered, producing drastic changes in the implant profiles, as shown for the high-dose implantation profiles in Fig. 5(a). At a dose of 3×10^{18} nitrogen ions/cm^2, approximately 75 nm has been sputtered from the surface, and the peak nitrogen concentration of approximately 200 at.% is still located below the surface. However, for doses above 5×10^{18} ions/cm^2, the peak nitrogen concentration of approximately 230 at.% lies at the surface of the sputtered substrate. Any further increase in dose beyond 5×10^{18} nitrogen ions/cm^2 will in essence be wasted effort, because sputtering will continue to remove previously implanted nitrogen ions as quickly as they are implanted.

A similar effect is observed for the titanium ion implantations shown in Fig. 5(b), except that the doses are decreased since the sputtering yield is 4.7 for 100 keV titanium ions incident on iron compared with 0.42 for 100 keV nitrogen ions. As shown by Fig. 5(b), doses in excess of 2×10^{17} titanium ions/cm^2 provide a concentration profile in which the peak concentration lies at the surface. It can also be seen that the peak titanium concentration at 2×10^{17}/cm^2 is approximately 20 at.% versus approximately 230 at.% for the high-dose nitrogen implants. Thus, the major effects of sputtering are to shift the location of the peak concentration closer to the exposed surface and to limit the maximum amount of material that can be implanted into near-surface regions.

Microstructural Properties of Implanted Regions

Near-Surface Region Defects. Implantation of energetic ions into components produces a large number of defects, such as vacancies, interstitials, and the implanted species, in the near-surface region that, depending on the deposition temperature, are potentially highly mobile even after they are in thermal equilibrium with the surrounding matrix. Although most of the vacancies and interstitials (and small clusters of vacancies and interstitials) generated in cascades diffuse through the matrix and recombine (for example, a vacancy and an interstitial may react to form the equivalent of a normal lattice site), sufficient numbers avoid recombination to alter the microstructure of the implanted region.

The mobile defects that survive react with existing microstructural features, such as dislocations, grain boundaries, free surfaces, secondary phases, and voids/bubbles, or combine with other defects to nucleate such microstructural features as dislocation loops, voids, and so forth. For example, Fig. 6 shows cross-sectional transmission electron microscopy (XTEM) micrographs of the near-surface region of nickel foils that were implanted at room temperature with energetic (500 keV) helium ions at two different doses: 2×10^{15}ions/cm^2 (Fig. 6a) and 1×10^{17}ions/cm^2 (Fig. 6b). At the lower dose, small dislocation loops can be observed in a region corresponding to a depth where the damage profile is at a maximum. At the higher dose, the dislocations extend to the surface of the foil (denoted as the interface in Fig. 6b).

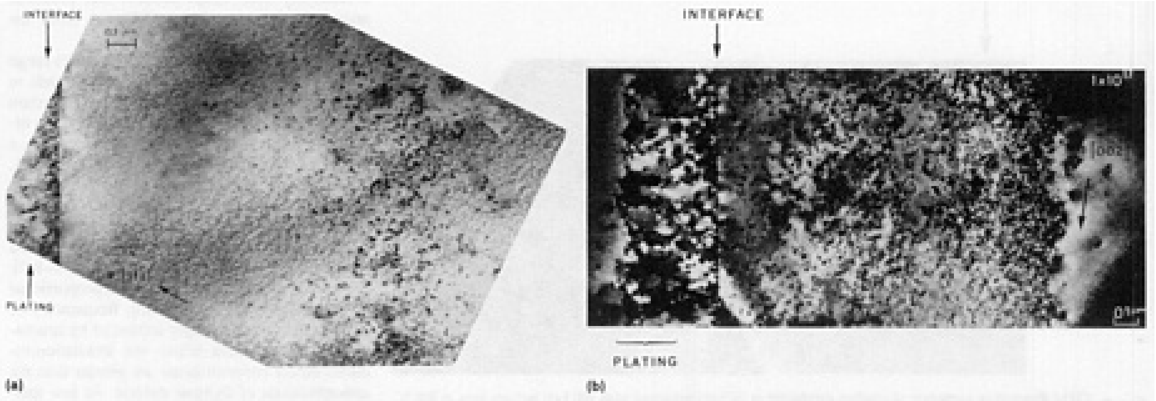

Fig. 6 XTEMs illustrating dislocations in near-surface regions of nickel implanted with 500 keV helium ions. (a) 2 × 10^{15}ions/cm^2. (b) 1 × 10^{17}ions/cm^2. Source: Ref 16

At higher temperatures and higher doses (500 °C, or 930 °F, and 5 × 10^{17}ions/cm^2, as shown in Fig. 7), the density of dislocations increases compared with those in Fig. 6. Typically, the dislocation density will increase at higher doses and decrease at higher temperatures, assuming other deposition conditions remain constant. In Fig. 7, the increase in the dose had a greater effect on the dislocation density than the increase in temperature.

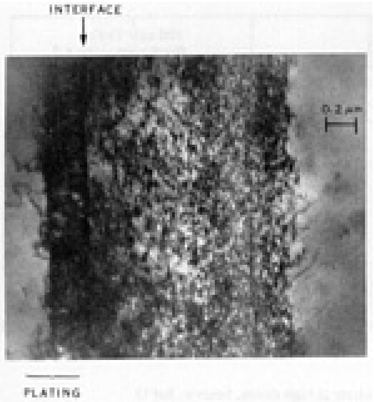

Fig. 7 XTEM illustrating high density of dislocations in a nickel foil implanted with 500 keV helium ions at 500 °C (930 °F) to a dose of 5 × 10^{17}ions/cm^2. Source: Ref 16

Under proper conditions, small three-dimensional voids and bubbles nucleate and grow in the irradiated region, as shown in Fig. 8. In this case (500 °C, or 930 °F, and 1 × 10^{17}ions/cm^2), the cavities range from 3 to 10 nm in size, depending on the depth, and occupy up to 1% of the volume. As higher doses are administered, the cavities grow and coalesce to form larger cavities. Eventually, the pressure inside the cavities, which are filled with the implanted helium ions, becomes sufficiently large to plastically deform the matrix above the cavities and form blisters* on the top surface.

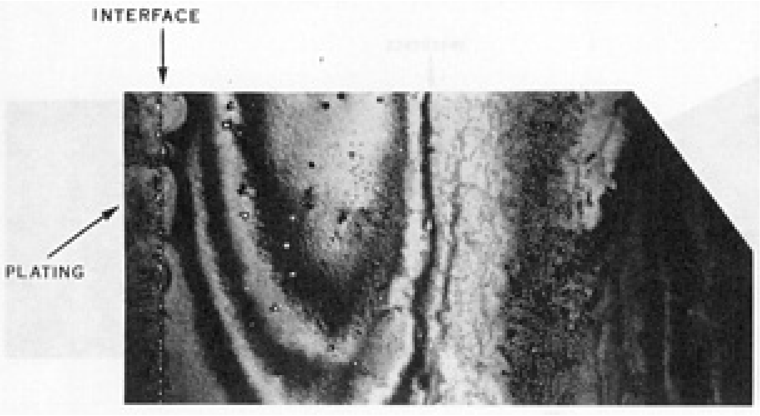

Fig. 8 XTEM illustrating presence of cavities produced in nickel implanted with 500 keV helium ions at 500 °C (930 °F) to a dose of 1 × 10^{17}/cm^2. Source: Ref 16

Crystalline-to-Amorphous Transformation. Ion implantation of energetic particles can sometimes change the crystalline nature of near-surface regions, producing amorphous layers (Ref 17, 18, 19, 20, 21, 22, 23, 24, 25) or, alternatively, can induce crystallization in near-surface regions of amorphous compounds (Ref 25, 26, 27). Several models have been proposed to account for the transformation from a crystalline to an amorphous state. One model suggests that amorphization is a result of rapid quenching (on the order of 10^{14} K/s) on thermal spikes produced in collision cascades (Ref 22). However, high-energy electron irradiations--which produce individual Frenkel-pair defects, but no cascades--are also capable of producing amorphous regions. Another model (applied to amorphization of ordered intermetallic alloys) treats amorphization as thermodynamically similar to melting phenomena and predicts that its onset occurs at a critical volume expansion, suggesting that amorphization is caused by a mechanical instability (Ref 17). The onset of amorphization and the degree to which it occurs depends on a number of factors, including temperature, implant species and substrate composition, dose, and dose rate.

Secondary Phase Formation. Under appropriate conditions, ion implantation can also lead to the formation of secondary phases that improve the tribological properties of the near-surface region. For example, nitride, carbide, oxide, and boride precipitates have been observed in both pure iron and steels after high-dose implantation with nitrogen, carbon, oxygen, and boron, respectively (Ref 28, 29, 30, 31, 32, 33, 34). In some instances, a postimplantation annealing treatment is employed; examples of such cases include the implantation of metallic ions such as molybdenum, iron, and nickel into metallic alloys, leading to the formation of intermetallic phases (Ref 35, 36, 37, 38), and the implantation of nitrogen into titanium alloys (Ref 39).

Modeling of Microstructural Changes. Research in the modeling of microstructural changes during irradiation has been quite extensive (Ref 39, 40, 41, 42). The overall approach utilizes the approximation of (quasi-) chemical or reaction-rate theory to calculate time- and spatially dependent concentrations of defects (for example, vacancies, interstitials, vacancy clusters, and dislocations), resulting in a set of equations of the type (Ref 43):

$$\frac{dC_j}{dt} = \Sigma_j\, w(k;j)C_k - \Sigma_k\, w(j;k)C_j + G_j - L_j \quad \text{(Eq 5)}$$

where C_j is the concentration of defects or clusters of type j (for example, voids containing j vacancies or dislocation loops containing j interstitials), $w(k;j)$ is the rate per unit concentration of transitions of defects or clusters of type k to type j, G_j is the rate at which defects or clusters of type j are formed directly (for example, formation of a dislocation loop directly from a collision cascade), and L_j is the loss rate of defects of size j by diffusion to sinks (for example, incorporation of vacancy clusters into large cavities). Calculation of the reaction parameters, $w(j;k)$, requires detailed knowledge of the physics of the different mechanisms involved in the evolution of the microstructure--for example, diffusion of the different species, interaction of different species, characteristics of defect generation, and interactions with defect sinks.

Solutions to these very approximate equations are straightforward (with many simplifying assumptions), but extremely time consuming because of the large number of coupled equations that must be solved for each type (and size *j*) of defect cluster (vacancies, interstitials, and implanted species). In compounds irradiated with energetic ions, the approach typically involves solving sets of coupled differential equations of the general form (Ref 43, 44):

$$\frac{\partial C_j(x,t)}{\partial t} = \frac{D_j \partial^2 C_j(x,t)}{\partial x^2} + S_j(x,t) \quad \textbf{(Eq 6)}$$

where C_j is the time- and depth-dependent concentration of elements (or defects) of type *j,* and S_j represents local rates of production and loss of species of type *j* by various processes, such as direct production of vacancies or interstitials during the slowing-down process of implanted ions, trapping of solute atoms at sinks, incorporation of defects into larger defects, and formation or dissolution of precipitates.

Solutions to the sets of differential equations (Eq 6) necessary to determine compositional changes in near-surface regions require modeling a number of physical phenomena (Ref 42, 45). These phenomena include (in addition to the chemical compositional change caused by addition of the implanted species) athermal processes, such as preferential sputtering and displacement mixing, and thermally activated processes, including radiation-enhanced diffusion, radiation-induced segregation, and Gibbsian adsorption.

Preferential sputtering is caused by differences in the sputtering yields of the different elements that comprise an alloy. Because of differences in the momentum transferred to elements of differing masses, the energy available to overcome a critical binding energy will differ from element to element in an alloy. In addition, differences in the chemical interactions of the different constituents in the alloy will result in different critical binding energies from element to element. As a result of these two effects, the individual sputtering yields of the different elements that constitute the material can differ, leading to an enrichment of elements with low yields and a depletion of elements with high yields. Because sputtered atoms typically originate from the first one or two monolayers, this is a relatively short-range process that produces near-surface compositions different from the bulk composition.

Gibbsian Adsorption. Another short-range process is Gibbsian adsorption, which tends to increase or decrease the concentration of certain alloying elements in the top surface layer in order to minimize the surface free energy. In a binary alloy consisting of elements A and B, Gibbsian adsorption would result in the top monolayer being enriched in either element A or B relative to the bulk composition. Because Gibbsian adsorption is dependent on the forward bulk-to-surface and backward surface-to-bulk jump frequencies, which in turn are proportional to the concentrations and jump frequencies of point defects, it is strongly enhanced by irradiation at temperatures where the irradiation-induced defect concentrations are greater than the concentrations of thermal defects. At low temperatures, Gibbsian adsorption is also affected by displacement-mixing-induced motion of atoms within cascades produced at the surface.

Gibbsian adsorption and preferential sputtering processes tend to counteract each other (Ref 45). For example, if in a binary alloy, element A is preferentially sputtered relative to element B, while Gibbsian adsorption produces a surface layer enriched (relative to the bulk composition) in element A, the two effects will counteract each other. However, if element B is preferentially sputtered while A is enhanced by Gibbsian adsorption, both effects will still counteract each other, because the increased concentration of A on the surface caused by Gibbsian adsorption temporarily produces a higher flux of A atoms from the surface, resulting in a pseudopreferential sputtering yield of A that counteracts the preferential yield of B.

Displacement mixing is an athermal process that results in a redistribution of alloying elements because of energetic displacement of atoms in collision cascades. The process can be modeled in a manner similar to diffusion, with the diffusion coefficient being dependent on the spatially dependent damage (or dpa) rate, the nearest-neighbor distance, and the number of atoms changing sites per dpa (Ref 46).

Radiation-Enhanced Diffusion. At elevated temperatures, thermally activated diffusional processes become dominant. The diffusional processes are enhanced by the excess concentrations of mobile vacancies and interstitials that survive recombination processes in cascades and at internal sinks. This process, termed radiation-enhanced diffusion, typically is dominant at temperatures between 0.2 and $0.6T_m$, where T_m is the melting point. Above approximately 0.6 T_m, the thermodynamic equilibrium concentration of vacancies becomes larger than the radiation-produced concentration of defects, and thus the diffusion coefficient is determined by conventional thermally produced vacancies. Below

approximately $0.2T_m$, the concentration of radiation-produced vacancies may be high, but the vacancies are not as mobile and the diffusion process is dominated by displacement mixing.

Radiation-Induced Segregation. In contrast to radiation-enhanced diffusion processes, which tend to flatten out composition gradients, radiation-induced segregation processes tend to increase local composition gradients (Ref 21, 44, 47). When the local concentration is increased above local solubility limits, radiation-enhanced segregation can lead to formation of phases normally not observed for the bulk alloy composition. Radiation-induced segregation is caused by a preferential coupling of alloying elements with defects to form mobile defect-solute complexes. Defect fluxes that arise from gradients in defect concentrations during irradiation thus induce net fluxes. Gradients in the defect concentrations that arise from spatially nonuniform production of defects, as well as gradients induced by the presence of sinks (the top surface, grain boundaries, or defect clusters such as dislocations, precipitates, or cavities), produce persistent fluxes of defects and thus a net flow of defect-solute complexes.

Radiation-induced segregation is strongly temperature dependent (Ref 48); at low temperatures, the high concentration of defects coupled with their low mobility increases their recombination, thus subduing their long-range migration and segregation. On the other hand, normal diffusion processes at high temperatures tend to flatten out compositional gradients, thereby also subduing segregation. Thus, radiation-induced segregation is dominant only at intermediate temperatures, where strong coupling of solute atoms with mobile defects exists.

An example of radiation-induced segregation is illustrated in Fig. 9, which shows the formation of (γ')Ni_3Si (25 at .% Si) from a nickel-silicon alloy with a bulk silicon concentration of 6 at .%. The top surface is the dominant sink for defects produced in near-surface regions, setting up a net flux of defects toward the surface. Because silicon in nickel-silicon alloys is preferentially transported in the same direction as the defect fluxes (Ref 21), silicon is transported to the surface of the implanted film. When the concentration of silicon exceeds the solubility limit (approximately 10 at .% in nickel-silicon), a coating of Ni_3Si forms on the top surface. Farther from the surface, grain boundaries and dislocation loops act as internal sinks for defects, producing net fluxes of defects (and Si) to them. Thus, the formation of Ni_3Si coatings on these sinks is also observed.

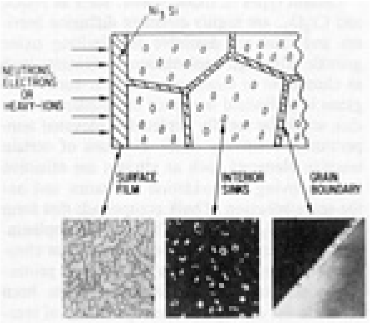

Fig. 9 Radiation-induced segregation in a Ni-6Si(at.%) alloy implanted with MeV nickel ions at elevated temperatures. Source: Ref 21

The important aspect of this discussion is that the microstructure of the implanted region can be significantly different from the starting microstructure. This can be attributed in part to the direct implantation of a foreign atom into the surface, thereby altering its chemical composition and microstructure. However, the microstructure can also be altered dramatically by the presence of mobile defects that interact by a number of mechanisms. This is readily seen in the alloy shown in Fig. 9, which was implanted not with foreign atoms, but with nickel atoms--the same element that constituted 94 at .% of the bulk composition. It is also important to note that the damage rate (or current density on the substrate) and temperature play major roles in determining the rates at which these processes occur.

Note cited in this section

* * Under most conditions encountered in the use of ion implantation in tribological applications, blister formation is not of concern, because the implanted species are either soluble in the matrix, are not gaseous, or, if they are gaseous (for example, implantation of nitrogen into titanium alloys), form solid compounds (for example, TiN).

Effect of Microstructure on Tribological Properties

The microstructural and chemical changes caused by ion implantation can significantly affect the tribological performance of engineering components. The extent of this influence depends on the type of wear/friction mechanisms present--for example, adhesive, abrasive, fatigue, or chemical interactions (Ref 49, 50, 51, 52, 53).

Adhesive and Abrasive Wear. For adhesive or abrasive wear conditions, it is important to note that when two macroscopically smooth surfaces are brought together, contact is made at isolated asperities on the mating surfaces. Models for adhesive or abrasive wear assume that the wear volume (or wear rate) is proportional to the number of asperities in contact (Ref 49), which in turn depends on the applied load and the yield strength of the asperities. The higher the yield strength, the fewer the number of asperities required to support the applied load. Thus, a lesser amount of material will be removed because of the lower number of asperities in contact. As a result, the wear volume is often found to be inversely proportional to the hardness (where the hardness is proportional to the yield strength) of the materials in contact. One mechanism by which ion implantation improves the wear behavior is strengthening of near-surface regions, which reduces the number of asperities that come into contact.

Strengthening Mechanisms. A number of mechanisms based on immobilizing dislocations have been examined in terms of their ability to strengthen ion-implanted surfaces (Ref 50). These mechanisms include cold working, substitutional solid-solution strengthening, interstitial solid-solution strengthening, second-phase strengthening, and phase transformations.

Conventional cold working of metals is often used to create a high density of tangled dislocations that restrict the motion of mobile dislocations by introducing strain fields and dislocation locks, thereby increasing the yield strength. As seen in Fig. 7, ion implantation can produce a high density of tangled dislocations. In addition, at lower temperatures, the implanted material will also have a high density of frozen-in point defects that can restrict the movement of dislocations. Both of these effects can lead to stronger near-surface regions with improved friction and wear performance.

Substitutional solid-solution strengthening is achieved by forcing impurity atoms with large atomic size differences with respect to the host atoms into substitutional lattice positions, resulting in large strain fields that the moving dislocations must overcome. The yield strength increases with the concentration of the solute and the atomic size difference. Because of its ability to implant virtually any element in the periodic chart, ion implantation is ideally suited to introducing misfitting atoms into the host matrix and thus strengthening the surface region. Ion implantation may even have an advantage in substitutional solid-solution strengthening, because it can introduce large concentrations of misfitting atoms in excess of those thermodynamically possible.

Interstitial solid-solution strengthening is another mechanism by which ion implantation can be used to strengthen near-surface regions and thus improve tribological performance. It is analogous to substitutional solid-solution strengthening; in this case, however, the interstitials are often mobile and diffuse to dislocations where they may become trapped and thus raise the energy barrier for dislocation motion. Carbon and nitrogen are two commonly implanted elements that act as interstitials in a number of alloys. It should be noted that a postimplantation, low-temperature aging treatment may be required for this effect to be observed (Ref 50).

Second-phase strengthening is another mechanism by which ion implantation can harden near-surface regions. In this case, the formation of fine precipitates (for example, by implantation of carbon into titanium alloys to form TiC precipitates) provide a barrier for dislocation motion and thus strengthen the surface.

Finally, phase transformation of a near-surface region to an entirely different phase by implantation of appropriate ions (for example, high-dose nitrogen implantations into chromium to produce CrN) can also improve tribological properties.

In this case, the improvement is not necessarily caused by limiting dislocation motion in the parent material, but rather by transforming a large portion of the implanted region into a different, stronger phase.

All of these mechanisms improve the wear behavior of implanted compounds by strengthening near-surface regions and thereby decreasing the number of asperities required to support the applied load. This in turn reduces the number of surface asperities involved in the wear process and hence the volume of material removed. This effect is important in both adhesive and abrasive wear environments. For adhesive wear, which is caused by local welding of asperities that come into contact, the ability of the asperities to adhere to one another is also critical. It has been suggested that surfaces composed of elements that are readily soluble in one another have high adhesion to each other and thus should have higher adhesive wear rates than two surfaces composed of elements that are insoluble in one another (Ref 51). For example, silver has limited solid solubility (<0.1%) in iron, while titanium is soluble (>1%) in iron; thus, a silver asperity should not weld itself to a mating iron asperity as readily as a titanium asperity. Ignoring other considerations (such as differences in the hardnesses of the asperities), it follows that greater adhesive wear losses can be anticipated for the titanium-iron couple than for the silver-iron couple. The importance of this observation is that ion implantation can also modify the chemical composition of near-surface regions (and hence surface asperities) in such a manner as to reduce the mutual solubility and adhesion of mating asperities.

Fatigue wear involves the initiation and propagation of cracks in materials by the application of cyclic stresses. The crack initiation stage is sensitive to the condition of the surface and thus can be modified by ion implantation. The crack propagation stage extends deep into the bulk of the substrate relative to the depth of the implanted ions and thus is normally not affected by ion implantation. It is during the crack initiation/nucleation stage, therefore, where ion implantation has a role in reducing fatigue by limiting dislocation movement in near-surface regions, thereby preventing persistent slip bands from forming a surface topography conducive to crack nucleation. The mechanisms by which dislocation motion and crack nucleation are reduced are similar to those described for strengthening near-surface regions. Thus, the methods for improving adhesive and abrasive wear properties are also applicable for improving fatigue life.

Corrosive wear processes involve the formation of corrosion products that remove surface material by mechanical action or by spallation arising from excessive internal stresses during film growth. Oxidation is one type of corrosion that can have a significant impact on the wear of components, particularly those fabricated from steels. In many instances, some degree of corrosion is desirable if the corrosion film prevents strong adhesion between mating asperities and if the corrosion film is hard and tenacious. However, if the corrosion film has high growth rates, or is brittle and does not adhere, the surface will undergo excessive wear.

Mechanisms Affecting Oxidation Resistance. Four mechanisms have been identified by which alloying (and hence ion implantation) can modify oxide growth rates (Ref 24): modification of the oxide defect structure, modification of the protective layer by incorporation of reactive elements, blocking mechanisms, and modification of the oxide plasticity. Modification of the oxide defect structure by ion implantation involves the incorporation of donor impurities that alter the electronic conductivity of the oxide, thereby modifying the electrochemical driving forces for diffusion of cations, anions, and electrons and hence growth of the oxide layer.

Certain types of oxide scales, such as Al_2O_3 and Cr_2O_3, are highly effective diffusion barriers and thus are desirable for limiting oxide growth. Although implantation of elements such as chromium or aluminum into near-surface regions is of limited use since the implanted species would be rapidly depleted at elevated temperatures, relatively small additions of certain reactive elements such as yttrium are effective for improving the oxidation resistance and oxide-scale adhesion of bulk compounds that form Al_2O_3 or Cr_2O_3 scales. Thus, while implantation of the large quantities of aluminum or chromium necessary to form a long-lasting protective scale may not be feasible, it has been effective for adding the small quantities of reactive elements required to enhance the adhesion and endurance of Al_2O_3 and Cr_2O_3 films.

Grain boundaries and dislocations act as paths for rapid diffusion of oxygen ions during oxidation. Ion implantation is effective in limiting diffusion along these paths by incorporating oversized solute atoms that are trapped at these fast-diffusion paths, thereby blocking the motion of oxygen ions.

The ability of an oxide film to relieve growth stresses will depend on its plasticity, which in turn depends on dislocation climb. Implantation of smaller cations that have a higher diffusivity than the host cation in an oxide lattice should therefore improve the ability of the oxide film to plastically deform, thus relieving growth stresses and thereby improving its adhesion to the underlying substrates. However, at higher doping levels, or for cations too small to be accommodated into the lattice, a second-phase oxide may form and pin dislocations, leading to lowered plasticity. It is also important to note that because plasticity is lower in stoichiometric oxides, doping in order to reduce defect concentrations (and hence diffusion) may actually reduce oxide plasticity.

Mechanisms Affecting Aqueous Corrosion. Implantation of atoms into near-surface regions also affects aqueous corrosion of metals by expanding the passive range of the surface, enhancing the resistance of the surface to localized corrosion, forming amorphous surface layers (thereby eliminating rapid corrosion at grain boundaries), shifting the open-circuit potential into a passive range where corrosion current densities are low, modifying the galvanic action of second-phase particles, and inhibiting the kinetics of cathodic reactions on the surface.

Although ion implantation can significantly affect the corrosive behavior of surfaces, its impact on corrosive wear is more complicated because of the mechanical stresses imposed on the contacting surfaces and because of frictional heating of asperities on a localized basis. Both of these factors affect the adhesion, ductility, and thermal expansion of the corrosion film. They are also important because of the cyclic nature of the wear process, particularly for sliding wear applications, which is affected by the growth rate of the corrosion film (that is, the amount of film growth that occurs between successive mechanical encounters of asperities).

Ion Implantation Equipment

Ion implanters consist of a number of components that generate, accelerate, and focus the ions onto a surface (Ref 54, 55, 56). Figure 10 illustrates several types of implantation systems, including mass-analyzed ion implanters (Fig. 10a), broad-beam implanters (Fig. 10b), and a relatively new type of system used in plasma-source ion implantation (PSII) (Fig. 10c).

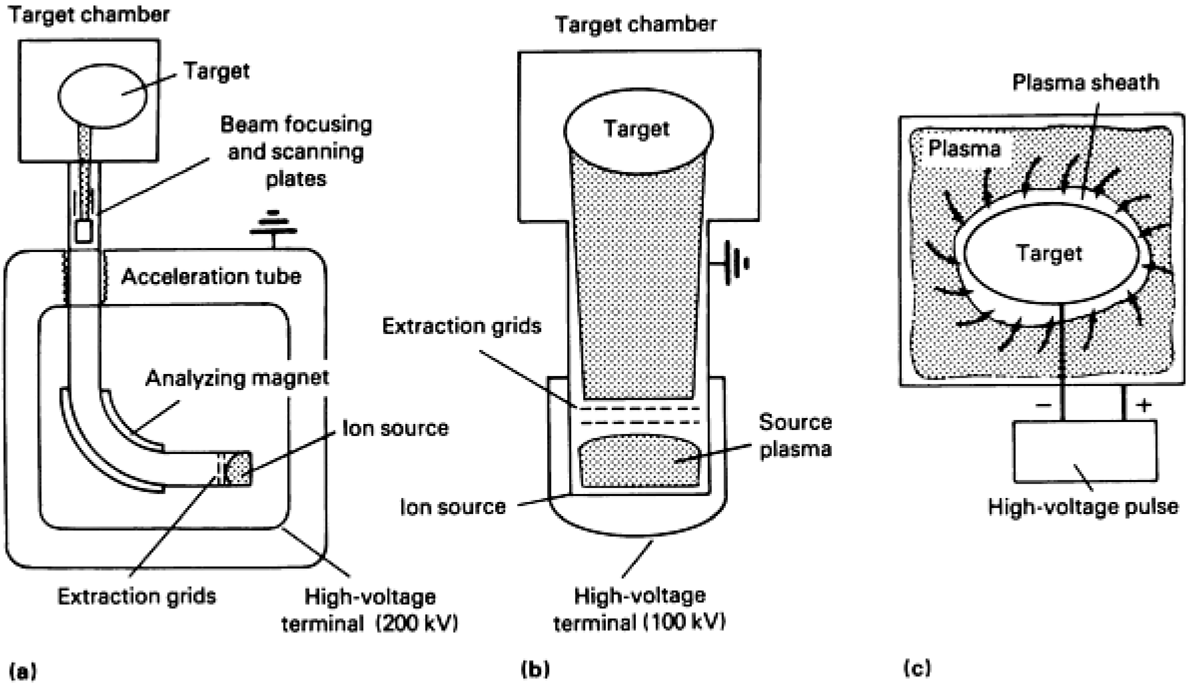

Fig. 10 Schematics of ion implantation equipment. (a) Mass-analyzed implantation. (b) Broad-beam implantation. (c) Plasma-source implantation

Ion Source and Ion Extractor. Ions are generated in the ion source. Ionization of gaseous elements, such as nitrogen, oxygen, or carbon (from methane, CH_4), is typically accomplished by introducing the gases into a source at moderate vacuum and bombarding them with energetic electrons. The electrons are supplied from an external source (such as a heated filament) or from a plasma generated from the working gas (N_2, O_2, or CH_4) by applying direct current, radio frequency, or microwave power to the source. For beams of elements that normally exist in a solid state, a volatile compound (for example, BCl_3 for boron, or a compound formed by passing a halide gas over heated metal) can be used as the working gas. Alternatively, a molten pool of metal can be generated in the source to provide partial pressure of elements (for example, titanium or copper), or physical sputtering processes can be built into the source to generate a plasma of the desired element that can be ionized by electron bombardment. The plasma is typically confined in the source by magnetic fields. Charged ions are extracted from the source by an ion extractor, which typically consists of a series of electrically biased grids with a number of apertures.

Analyzing Magnet. Because some source designs produce unwanted ions (as in the case of sputter sources that use inert gases such as argon as the working gas, thus producing argon ions in addition to the desired ion), they typically include an analyzing magnet (Fig. 10a), which selects the desired ions from the beam of ions extracted from the source. In other designs (Fig. 10b), a high-purity source of vapor exists, making it unnecessary to mass analyze the extracted beam (unless selection of a particular charge state of the ions is desired). Recent advances in broad-beam source technology indicate that high-current ion sources for both gaseous and metallic ion beams can be achieved (Ref 57, 58, 59).

Acceleration Tube and Target Chamber. The ion source, extraction grids, and analyzing magnet are typically floated at voltages ranging from 25 to several hundred kV for most commercial implantation systems. The next component in the systems shown in Fig. 10(a) and 10(b) is an acceleration tube, which accelerates the ions to ground potential.

After exiting the acceleration tube, the ion beam is focused, steered, and rastered to achieve the desired beam shape and current density. The last component of the implantation system is a target chamber, consisting of a vacuum enclosure and equipment for manipulating the parts to be implanted in the beam of energetic ions. Mechanical motion of the substrates coupled with beam rastering generally is used to obtain the desired doses. Beam rastering is not used in broad-beam implanters. In some instances, masks must be placed in front of parts with complex shapes to limit implantation at off-normal directions and thus minimize sputtering effects.

System Differences. The major difference between the systems illustrated in Fig. 10(a) and (b) involves accelerating voltages and beam current. Broad-beam implantation systems typically operate at acceleration voltages up to 100 kV and can deliver large beam currents (in excess of 500 mA for gaseous ions and 50 mA for metallic ions) on target. Mass-analyzed implanters designed for commercial applications typically operate at acceleration voltages up to 200 to 400 kV, with beam currents up to 10 to 20 mA on target. Another difference is the size of the beam on target. As the name implies, the size of the ion beam on target for broad-beam implanters can be quite large (in the range of 0.5 m, or 1.5 ft, diam), while mass-analyzed beams are typically on the order of 10 mm (0.4 in.) diam. As a result, mass-analyzed beams are usually rastered over the component to be implanted, whereas broad-beam ion beams are not.

The PSII system illustrated in Fig. 10(c) is relatively new. Rather than extracting and accelerating an ion beam from a source and impinging the beam on the part in a target chamber, the PSII process places the part inside a plasma and repetitively pulses the part to be implanted at high negative voltages (typically -100 kV) to obtain a flux of energetic plasma ions on it (Ref 60). Because the plasma surrounds the part, and because the ions are accelerated normal to the part surface, the plasma-source implantation occurs over the entire surface, thereby eliminating the need to manipulate the part in front of the ion beam as in Fig. 10(a) and (b).

In addition to the basic components illustrated in Fig. 10, most implanters have equipment for monitoring and controlling the ion beam. Such diagnostic equipment typically consists of components for monitoring the ion dose on target, current density and beam shape, and substrate temperature, and for cooling and heating the substrate.

Applications of Ion Implantation

Commercial use of ion implantation for tribological applications dates back to the mid-1970s. Many applications are related to improvements in tooling used in metalforming and cutting operations. The initial cost of the tooling and increased productivity due to decreased downtime for changing tools easily offset the added cost of implantation. In these applications, use of implanted tools results in longer tool life, improved surface finishes of worked material, reduced pickup or transfer of material, easier release from molds, and improved corrosion resistance. End-use applications of ion implantation continue to grow in areas where the components are small and the implantation cost per part is low, where replacement cost is high, or where long shelf life (corrosion resistance) is required.

Selection of the dose and the type of ion to be implanted depends greatly on the tribological conditions. These conditions include not only the composition of the components but also the environment, operating temperature, and stresses. In most cases, the selection of the implantation conditions is empirically determined. Table 2 lists some of the ions that improve wear (adhesive/abrasive, fatigue, and corrosive) and friction properties of different alloys.

Table 2 Elements implanted to improve wear and friction properties

Alloy	Implantation element				Ref
	Adhesive and abrasive wear	**Fatigue wear**	**Corrosion and oxidation wear**	**Friction**	
Aluminum alloys	N		Mo		50, 61
Beryllium alloys	B				50, 61, 62
Ceramics	N, O, Cr, Zr, Y	N, O			61
Cemented carbides (WC)	N, Co				61, 62
Copper alloys	B, Ti	Al	Al, Cr		50, 61, 62, 63
Steels	N, Ti + C, Y, Ta + C	B, N, Ti	Cr, Ta, Y	Ti, Ti + C, Ag, Sn, Au	50, 52, 61, 62, 63
Superalloys	C, N, Y, Ti + C	C	Al, Y, Ta, Pt, Au, Ce		50, 61, 62
Titanium alloys	B, C, N	C, N, Al	C, N, Pd	Ag, Sn	50, 61, 62, 63
Zirconium alloys	C, N, Cr + C		Cr, Sn		61, 62

Most implantations for tribological applications where chemical rather than microstructural changes are required use doses in the range of 10^{17} to 10^{18}ions/cm^2. Under typical implantation conditions at nominal room temperature, sputtering limits the maximum concentration of implanted species that can be achieved. Thus, implanting to doses much greater than approximately 1×10^{18}ions/cm^2 (depending on the sputtering yield) is largely useless.

An exception to this dose limit can occur if the implantation is performed at elevated temperatures or at ultrahigh current densities that produce high substrate temperatures or that induce radiation-enhanced diffusion and thus permit mobile implanted species to diffuse deeper into the substrate. As an example, broad-beam implantation of type 304 stainless steel (Ref 31) with 60 keV nitrogen ions to a dose of 1×10^{19} ions/cm^2 at an ultrahigh current density of 500 μA/cm^2 (3.2 mA/in.^{2}) in a pulsed manner to control the substrate temperature to approximately 500 °C (930 °F) resulted in a nitrogen concentration level of 15 to 20 at.% that extended to depths greater than 10 μm. This is approximately 100 times deeper than the projected range (Fig. 3a) of 60 keV nitrogen ions in iron, indicating that thermal and/or radiation-enhanced diffusion allowed the nitrogen to penetrate farther into the substrate. In contrast, implantation at lower current densities (100 μA/cm^2, or 645 μin.^{2}) resulted in lower substrate temperatures (approximately 380 °C, or 715 °F), and in concentration profiles that more closely matched those predicted by athermal calculations.

For typical ion implantation procedures performed at nominal room temperature, Table 3 lists approximate ion-dose regimes where different hardening mechanisms are expected to be first observed. For conventional cold-working mechanisms, it is evident that heavy ions are more effective, because they displace atoms much more readily than light ions. For the other mechanisms, a certain concentration of foreign species is required, and thus higher implantation doses must be used to achieve the desired result.

Table 3 Approximate dose regimes for effective hardening during ion implantation

Hardening mechanism	Dose, ions/cm^2	
	Light ions (C, N)	**Heavy ions**
Cold working (defect/dislocation tangles)	10^{14}-10^{16}	10^{13}-10^{16}
Interstitial solution hardening	10^{16}-10^{17}	. . .
Substitutional solution hardening	. . .	10^{16}-10^{17}
Second-phase hardening	10^{17}-10^{18}	10^{16}-10^{17}
Phase transformation	10^{17}-10^{18}	10^{17}-10^{18}

Specific examples of applications of ion implantation in metalforming and cutting are given in Table 4, and Table 5 lists examples of end-use applications. In many of the applications noted in Tables 4 and 5, the implanted components generally operate at relatively low temperatures, where microstructural and chemical changes caused by implantation are stable. Thus, operating conditions, particularly the nominal bulk temperature and flash temperature of the asperities, can affect the viability of a particular implantation treatment for improving the tribological performance of a given component. A treatment that works in one situation to reduce adhesive wear may not work in another situation because of different tribological conditions. As a result, it is crucial to understand the tribological environment (loads, stresses, bulk

and flash temperatures, and material properties) and how that environment can influence the microstructural and chemical changes induced by implantation processes.

Table 4 Examples of ion implantation in metalforming and cutting applications

Part	Part material	Process	Work material	Wear mechanism	Ion	Energy, keV	Benefit	Ref
Tool inserts	TiN-coated tool steel	Machining	4140	Abrasion	N	80	3× life	63
	TiN-coated WC	Machining	321 SS	Abrasion	N	80	2× life	63

Laser Surface Processing

Khershed P. Cooper, Naval Research Laboratory

Introduction

HIGH-POWER LASERS have been used to process materials to improve their wear resistance since the late 1960s. Laser surface processing encompasses established techniques, such as laser transformation hardening, which has achieved production-level capabilities, and techniques that are still in a development stage, such as laser cladding, which is emerging as a viable alternative to other hard-facing processes, such as plasma deposition.

The laser beam is a chemically clean light source that delivers a precisely controlled quantity of energy to localized regions. By this means, only those areas exposed to wear are processed for improvement in wear resistance. The laser beam is easily maneuvered by optical elements and can be adapted to automation. High power densities and low interaction times result in rapid heating and cooling, which produces a shallow heat-affected zone, low distortion of the workpiece, and minimal deterioration of bulk properties. Rapid solidification effects produce refined and novel microstructures that result in improved properties.

Laser Characteristics. Most laser surface processing utilizes continuous wave (CW) lasers. In limited instances, a pulsed laser is used, for example, to harden the tip of a tool bit. The most common lasing medium for materials processing is CO_2 gas. The 10.6 μm wavelength CO_2 laser couples poorly with metals, but generally has a high average power output between 1 and 25 kW. With the help of radiation-absorbing agents, metals with high melting points can be processed. The excitation-mode structure of the CO_2 laser is usually "doughnut-shaped," which, after being modified by optics, produces a near-Gaussian energy distribution on the sample surface.

In its simplest form, laser-material interaction involves the heating and melting of a moving substrate with a stationary beam. This "spot" energy source is typically 1 to 2 mm (0.04 to 0.08 in.) in diameter and produces a melt pass with a width from 2 to 3 mm (0.08 to 0.12 in.). By overlapping several of these passes, usually by 25 to 50%, larger areas can be processed. In addition to being slow, this technique can often cause tempering and cracking within the overlap regions, thereby lowering the quality of the product surface.

An alternative method is the use of beam-shaping optics to produce broad energy distributions on the sample surface. Scanning the beam over the substrate, either by oscillating a flat mirror or by rotating a polygonal mirror, produces a "line" energy source. An integrated beam, which is formed by an integrated mirror, produces a "rectangular" energy source. When interacting with a moving workpiece, either energy source produces a strip of modified surface. The use of beam-shaping optics represents an efficient method of achieving the hardening of selected areas on the workpiece, which is required by most wear applications.

In addition to shaping the beam, optical elements can be designed and arranged to direct it onto the workpiece in many ways. For example, a reflecting mirror can be used to project the laser beam onto the inner wall of a rotating tube. Toric mirrors also can be designed to form a continuous band of radiation to treat inner or outer surfaces of cylinders and cones. Prisms can also be used to split the laser beam and direct the two parts at different angles to a shaped surface, such as a gear groove.

Laser surface modification techniques that are used to improve the wear resistance of metals include transformation hardening, melting, alloying, cladding, and particle injection. The processing conditions, examples of microstructures, wear characteristics, and applications associated with each technique are discussed in detail in this article.

Parameters for laser surface processing depend on the type of modification (for example, transformation hardening or cladding) and thermophysical properties of the material (such as thermal diffusivity or heat capacity). The important laser processing parameters are power density and interaction time, which are functions of the average laser power, the sample translation rate, and the beam diameter. Rapid melting or glazing requires either high power densities and short interaction times or high power levels and high translation rates, whereas transformation hardening requires either low power densities and long interaction times or low power levels and low translation rates.

Other processing variables, such as the composition of the atmosphere or the rate of material addition, depend on the particulars of the process. For example, consideration must be given to the need to protect against oxidation and the desire to have certain characteristics of the surface layer, for example, thickness, composition, and microstructure. Depending on the processing conditions, surface layer thicknesses can range from 0.01 to 5 mm (0.0004 to 0.2 in.). The longer the interaction time, the deeper the treated layer will be.

Processing parameters for cladding and surface melting typically modify the surface to depths from 0.5 to 5 mm (0.02 to 0.2 in.) with microstructures that are similar to welded structures. The parameters for rapid surface melting or glazing modify surfaces from 0.02 to 0.6 mm (0.0008 to 0.02 in.) deep, but the resulting rapid quench rates from 10^5 to 10^7 K/s allow for the synthesis of novel microstructures. Material addition practices will depend on the specific laser surface processing technique under consideration. Steen (Ref 1) has summarized the process variables and their methods of measuring (Table 1).

Table 1 Process variables and methods of measuring

Process variable	Method of measuring
Laser power	Flowing cone calorimeter
Beam diameter	Rotating rod
Beam mode structure	Acrylic prints, fluorescent screens
Sample speed	Electronic timer
Material addition flow rate	Load cell on feed hopper, acoustic emission sensor on feed line
Particle velocity	Rotameters, fast-action photography, photographic tracer technique

Laser Transformation Hardening

Processing. The wear resistance of highly stressed ferrous alloy components, such as gears and bearings, can be improved by transformation hardening. Because ferrous materials are very good heat conductors, the high heat fluxes generated by lasers are most suitable to heat the surface layer to austenization levels without affecting the bulk temperature of the sample. The ensuring self-quenching is rapid enough to eliminate the need for external quenching to produce the hard martensite in the heated surface. Because ferrous alloys have high reflectivity, absorptive coatings such as manganese phosphate and graphite are applied to the workpiece for efficient laser heating. Most of these coatings burn off and normally do not affect the microstructure. Processing conditions for laser transformation hardening are typically power densities that range from 5 to 100 MW/m^2 (3.2 to 64.5 kW/in.^{2}) and interaction times ranging from 0.01 to 10 s. Usually, inert gas shielding is used.

A rectangular beam is often used for laser transformation hardening. According to Sandven (Ref 2), the case depth depends on the hardenability of the material and rarely exceeds 2.5 mm (0.1 in.). For example, in medium-carbon steel, a case depth of 1.25 mm (0.05 in.) is common, whereas in mild steel, a case depth of only 0.25 mm (0.01 in.) is possible for the same processing conditions. Because of the rapid heating and cooling rates, steels that are not hardenable with other heat treatment methods can be hardened with laser processing.

The hardened case depth and the transition zone also depend on the coarseness of the initial microstructure. With a coarse starting structure, the case depth is shallower and the transition from full martensite hardness to base metal hardness is more gradual than with a fine starting structure. According to Seaman (Ref 3), coarser structures provide longer diffusion paths in which to achieve uniform austenization. To facilitate complete transformation during laser transformation hardening, materials with fine starting microstructures, such as closely spaced pearlite, are recommended. In many cases, the part is conventionally quenched and tempered prior to laser processing.

Because laser processing can occur too rapidly to allow for complete diffusion of carbon in the austenite, the interaction times are kept longer. The laser power density is kept low to prevent surface melting, which can form harmful eutectic carbides and can blunt the sharp edges and corners of a complex workpiece. Melting can also change the surface topography, requiring postmachining. The careful design of the beam shape and energy distribution can minimize surface melting problems. During closure of a circular hardening pass or during overlapping of several passes, back-tempering can occur in the overlapped regions. If this is detrimental, then the overlapped area should be located in a position of low service wear.

For example, the interior walls of internal combustion engines can be hardened by spiral laser passes, which results in some unhardened regions without causing harmful effects. It has been claimed that the use of a laser-hardened spiral on a shaft that runs in a bearing results in one-third of the wear that is experienced when using a uniformly induction-hardened shaft, because, in the former case, the wear debris becomes safely embedded in the softer interspiral regions (Ref 4). In one line-hardening procedure for plain carbon steels, the laser-heated areas rise above the sample surface and act as hard bearing tracks in a tough material, because of the volume expansion of the martensite (Ref 5).

In laser transformation hardening, the thermal energy is generated by absorption of the laser radiation at the surface. The increase in temperature below the surface is by conduction only. If the rate of heat absorption and the thermal properties of the sample are known, then the temperature distribution in the sample can be calculated. By this means it is possible to determine the optimum laser processing conditions.

Heat flow expressions are available in the literature to make these calculations (Ref 2). The simplest expression assumes heat flow to be one-dimensional, normal to the surface. In reality, heat diffuses in all directions and is lost by radiation from the surface. Furthermore, the thermal properties are temperature dependent, and the workpiece is not always large enough to be considered an infinite heat sink. These factors need to be considered when determining the temperature distributions. However, for high processing speeds, thick samples, and large beam sizes, the one-dimensional model gives good estimates. Using the one-dimensional heat flow model, cooling rates can also be calculated. When used in conjunction with cooling transformation diagrams, the adequacy of the self-quenching for hardening can be predicted.

Examples of Laser-Hardened Surface Microstructures. In ferrous alloys, the formation of martensite is essential for hardening and increased wear resistance. In laser-hardened carbon steels, such as 1018 and 1045, the relative amounts of ferrite and martensite depend on the carbon content. In laser-hardened alloy steels, such as 4340, 8620 and 52100, a very fine martensite forms (Ref 6). Courtney and Steen (Ref 7) found that in a 0.36% C steel, the microstructure was dependent on sample translation rate. At low sample speeds, areas of high-carbon martensite formed, whereas at high sample speeds, an inhomogeneous martensite mixed with austenite formed.

In cast irons, laser heat-treated surfaces appear in light contrast, as shown in Fig. 1(a) for gray iron and in Fig. 1(b) for ductile iron (Ref 8). The microstructure of laser-hardened gray cast iron is generally fine martensite that contains flake graphite, as shown in Fig. 2(a) (Ref 8). Acicular bainite can sometimes occur in the martensite matrix (Ref 9). The microstructure of laser-hardened ductile iron is also fine martensite, but contains "bull's eye" graphite nodules, as shown in Fig. 2(b) (Ref 8). A closer examination of Fig. 2(b) reveals a narrow region of martensite between the graphite nodule and the ferrite ring, which indicates the extent of carbon diffusion occurring during processing.

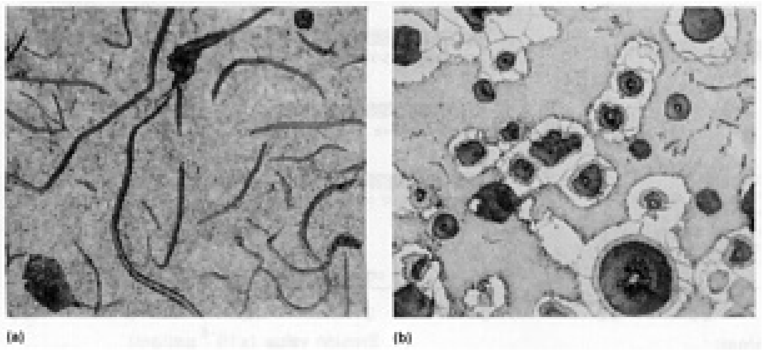

Fig. 2 Microstructures of laser-hardened cast irons. (a) Gray iron. (b) Ductile iron. Source: Ref 8

According to Molian and Baldwin (Ref 10), the extensive case that developed during laser hardening of gray and ductile irons was made up of sequential regions with varying degrees of microstructural modification. The region just below a very thin melt zone contained plate martensite, retained austenite, and graphite, whereas the region just above the base metal contained a mixture of refined martensite and untransformed pearlite.

Wear Behavior of Laser-Hardened Surfaces. Gnanamuthu (Ref 11) reported pin-on-disk wear test results on laser-hardened AISI 1045 steel specimens. After testing for 10 h, the weight loss that was due to wear in the laser-treated samples ranged from 0.6 to 1.4 mg (2.1 to 4.9 × 10^{-5} oz), whereas the weight loss in the untreated samples was 4.8 mg (1.7 × 10^{-4} oz). Using a two-disk machine, Lu and Zhang (Ref 12) found that laser hardening significantly improved the wear resistance in normalized or austempered ductile iron by the formation of strain-induced martensite. From their study of pin-on-disk wear behavior of laser-hardened gray and ductile cast irons, Molian and Baldwin (Ref 10) found an improvement in scuffing and sliding wear resistance with an increase in case depth as shown in Fig. 3. On the same samples, erosive wear test results showed that the erosion rate depended on the surface hardness and the case depth, as shown in Fig. 4, and increased as the matrix microstructure varied from ledeburite to tempered martensite to pearlite (Ref 13).

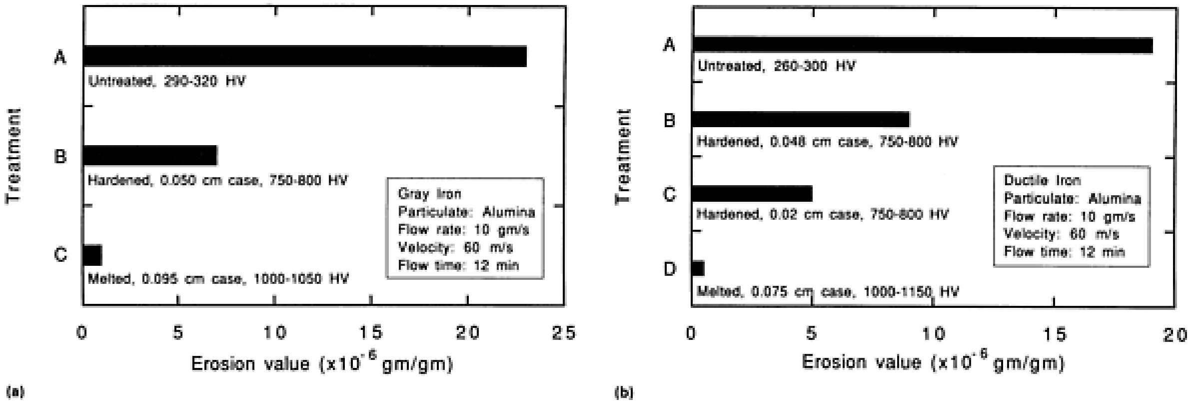

Fig. 4 Erosive wear behavior of laser-hardened cast irons as a function of surface hardness and case depth. (a) Gray iron. (b) Ductile iron. Source: Ref 13

Tomlinson *et al.* (Ref 14) observed that besides reducing wear, laser hardening of flake graphite iron resulted in very little plastic deformation, no graphite deposition on the opposing wheel, and no adhesive damage. Trafford *et al.* (Ref 15) used a reciprocating pad-on-plate technique to evaluate the wear resistance of laser-processed gray iron and found that fully martensitic and surface-melted ledeburite microstructures had the lowest wear rates (Fig. 5).

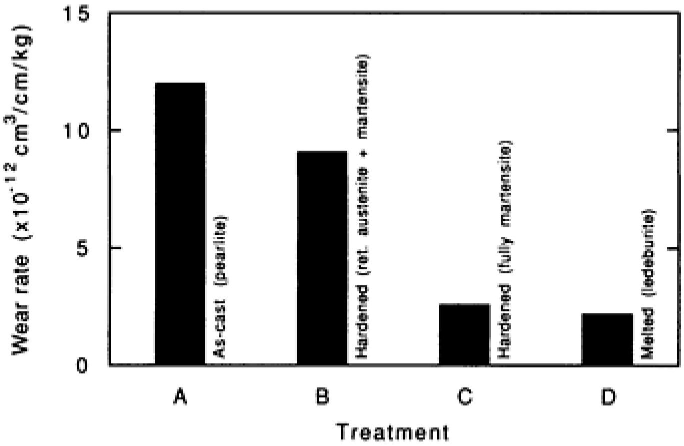

Fig. 5 Abrasive wear rates in gray iron as a function of microstructure arising from various laser-hardening treatments. Source: Ref 15

Applications of Laser Transformation Hardening. Wineman and Miller (Ref 16) describe laser hardening of selected areas on an automotive power steering gear housing made of ferritic malleable cast iron. The bands of highest wear on the housing were laser hardened to 60 HRC by transforming a ferritic-pearlitic-temper carbon microstructure to temper carbon surrounded by martensite. No distortion was measured and wear was reduced by 90%. Previously, the part was nitrided, requiring a costly annealing operation to maintain concentricity. Yessik (Ref 17) describes laser hardening of a 4150 steel gear spline using a long depth of field and a soft focus to ensure simultaneous hardening of tip and root.

Sandven (Ref 2) describes a cast iron cam-shaft lobe that was laser hardened by rotating under a rectangular beam. The cam-shaped lobe was hardened to a constant case depth of 1 mm (0.04 in.) by varying the angular speed from 12.5 mm/s (0.5 in./s) at the cylindrical portion to 3 mm/s (0.12 in./s) at the flat portion. The laser-hardened surface required no postmachining, but induction hardening had been used previously, causing considerable distortion that required postmachining.

Other laser hardening examples given by Sandven (Ref 2) are an SAE 1045 steel gear and a 25 mm (1 in.) diam 4140 steel cylinder. The gear was hardened to 60 HRC by splitting the laser beam using a prism and directing each half to the gear groove in the form of a 12.5 mm (0.5 in.) square shape. Using a toric mirror, a 5 mm (0.2 in.) wide band of laser energy was formed to harden the conical top of the cylinder. The entire cone was treated by translating the workpiece axially. Because the focusing distance varied along the conical top, the laser power was increased from 3.5 kW at the tip to 7.6 kW at the cylindrical portion.

By properly shaping the laser beam, Seaman and Gnanamuthu (Ref 18) describe hardening of only the sides of the grooves in a gray iron piston ring. Melting of the sharp corner was avoided by precisely directing the beam. This is an inaccessible area that would have been difficult to harden by conventional means. The authors also describe laser hardening of the faces of a malleable cast iron spacer to a hardness of 58 HRC. In this case, the laser beam power was ramped down by an aperture to minimize tempering where the circle closed out.

La Rocca (Ref 19) reports laser hardening of gear and rack teeth at an Italian automotive manufacturer. An oscillating beam and beam splitting mirrors were used to harden the two faces of each tooth. Hardened cases of 50 to 55 HRC were obtained on C-45 steel steering racks. At the electromotive division of an American automotive manufacturer, cylinder liners in high-performance turbocharged diesel engines were made more scuff-resistant by using a 10 mm (0.4 in.) diam laser beam (Ref 20). The entire surface was treated by continuously rotating the component and overlapping several paths. No heat treating had been performed previously, and laser hardening improved the service life.

Laser Melting

Processing. Laser melting requires higher power densities than the levels used for laser transformation hardening. The workpiece is often made absorptive either by using coatings similar to those used for laser heating or by increasing surface roughness, for example, by sand blasting. Laser melting can harden alloys that cannot be hardened by laser transformation hardening. In ferritic malleable gray iron, melting enhances the diffusion of carbon, and the ensuing rapid quench produces a hardened region.

One problem with laser melting is that once the melt forms, the absorptive coating is removed, and the melt pool becomes reflective. Water-cooled, optical feedback systems described by Steen (Ref 21) can be used to increase the coupling efficiency. An oscillating beam can be employed to melt larger areas, which makes the mode structure of the beam less important.

According to Bergmann (Ref 22), the production of a crack-free, oxidation-free, and porosity-free layer requires special arrangements for the shielding gas, which allow for changes in the gas flow rate, angle of impingement, and shape of the gas jet. Proper direction of the gas jet can prevent massive plasma formation, which is often responsible for the formation of cracks, as well as oxidation. Processing conditions for laser melting are typically a power density from 10 to 3000 MW/m^2 (6.5 to 1935 $kW/in.^2$) and an interaction time from 0.01 to 1 s. Inert gas shielding is used to prevent oxidation of the surface.

Examples of Laser-Melted Surface Microstructures. Microstructural changes with laser melting are in the forms of grain refinement, solid solutions, and fine dispersions of precipitates. All of these can contribute to the hardening and strengthening of the surface. Laser-melted surfaces of cast irons appear dendritic, as shown in Fig. 6(a) for gray iron and in Fig. 6(b) for ductile iron (Ref 8). Below the melt zone is the heat-affected zone, which appears in lighter contrast in Fig. 6.

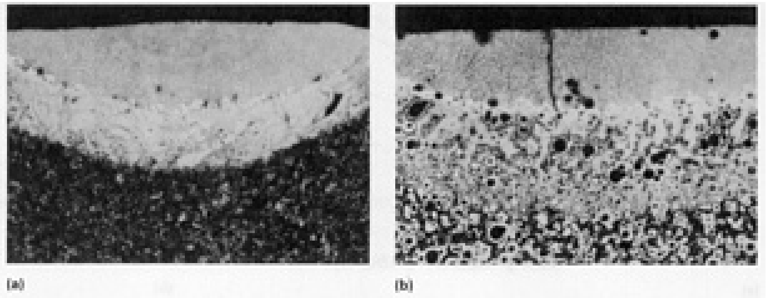

Fig. 6 Cross sections of laser-melted cast iron surfaces. (a) Gray iron. (b) Ductile iron. Source: Ref 8

In the solidified melt in cast irons, a ledeburite (mixture of austenite and cementite) structure generally forms (Ref 21, 22). Hardening is caused by graphite dissolution to form cementite and austenite transformation to martensite. Molian and Baldwin (Ref 10) described the formation of predominantly dendritic ledeburite with small amounts of plate-like, high-carbon martensite and retained austenite in the melt zone in gray and ductile irons.

Chen *et al.* (Ref 23) determined that microstructures in laser-melted ductile iron depended on the solidification rate. Dendritic retained austenite with a continuous interdendritic carbide, with a microhardness from 400 to 650 HV, formed at high solidification rates. A lamellar mixture of ferrite and cementite plates, with a microhardness from 1000 to 1250 HV, formed at low solidification rates.

Bamberger *et al.* (Ref 24) found that in laser-melted gray cast iron, full dissolution of the graphite occurred, leading to the formation of hot tears on the surface. On the other hand, in laser-melted nodular cast iron, partial dissolution of the graphite occurred, resulting in increased ductility and no hot tearing. Steen (Ref 21) found that martensitic structures were formed in some stainless steels, whereas fine carbide dispersions were formed in tool steels.

In laser-melted titanium alloys, highly dislocated, fine, plate-like martensitic structures were reported by Steen (Ref 21). In Ti-15Mo, the crystal growth was epitaxial from the β grains in the substrate in a direction normal to the interface (Ref 25). In Ti-6Al-4V, β martensite transformation in the solid state occurred upon rapid cooling. Plates of a twinned substructure were common. In Ti-10V-2Fe-3Al, martensite with some α formed upon solidification.

Wear Behavior of Laser-Melted Surfaces. Bergmann (Ref 22) has summarized the wear properties of laser-melted cast irons. For laser-melted gray iron containing flake graphite in a pearlitic matrix, the dry pin-on-disk test demonstrated that the wear behavior improved by an order of magnitude and was better than a fully martensitic structure. In a test involving rolls that ran against one another with a fixed relative slip, it was found that the wear resistance of laser-melted ductile iron was superior to that of: 0.6% C steel, case-hardened 16MnCr5 steel, nitrided or carburized 16MnCr5 steel, and a gas tungsten arc welded melted surface.

Ju *et al.* (Ref 26) reported significant improvement in erosive wear behavior in laser-melted ductile and gray irons, as shown in Fig. 7. This improvement was due to the presence of mechanically metastable austenite that transforms to martensite when plastic deformation of the near-surface region occurs during wear.

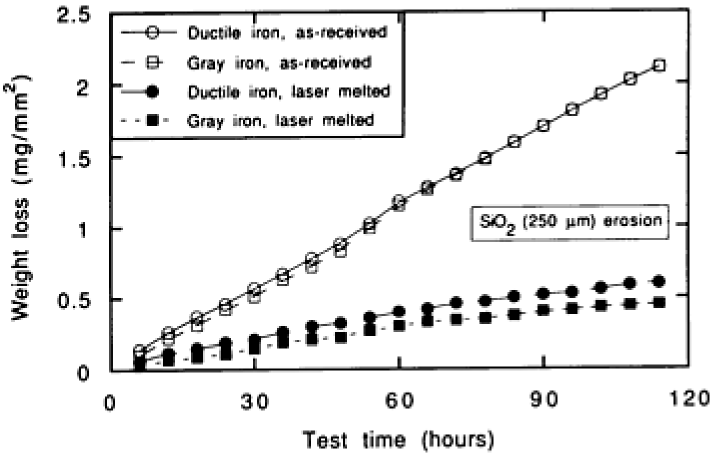

Fig. 7 Erosive wear behavior of as-received and laser-melted gray and ductile irons. Source: Ref 26

Tomlinson *et al.* (Ref 27) reported that laser melting reduced the amount of cavitation erosion of gray cast iron in distilled water by a factor of 0.3, and, in 3% saltwater, by a factor of 0.57.

Kusinski and Thomas (Ref 28) found that by laser melting, the wear resistance of Fe-Cr-Mn-C steels was improved by a factor of 1.4 to 1.6 over that of conventionally hardened steels only when the melt zone was shallow. This improvement was due to the formation of a stress-induced martensite with a highly dislocated lath and internally twinned structure.

De Beurs and De Hosson (Ref 29) found stress-induced hardening in laser-melted chromium steel. During wear, the austenite structure with segregated M_3C carbides, which had a microhardness of 550 HV, transformed to αmartensite, which had a microhardness of 900 HV. In laser-melted steels, the improvement in wear resistance was best when the dendritic growth of the austenite was perpendicular to the surface, because in this orientation the concentration of carbides was the highest (Ref 30).

Hsu and Molian (Ref 31) reported that the tool life of laser-melted M2 steel tool bits was from 200 to 500% higher than if they were conventionally hardened using catastrophic failure criterion (Fig. 8a). For laser-melted M35 steel tool bits, the tool life was from 20 to 125% higher than if they were conventionally hardened using flank wear failure criterion (Fig. 8b). High-alloy martensite, fine austenite grain size, and finely dispersed carbides all contributed to high hardness, good toughness, and low coefficient of friction.

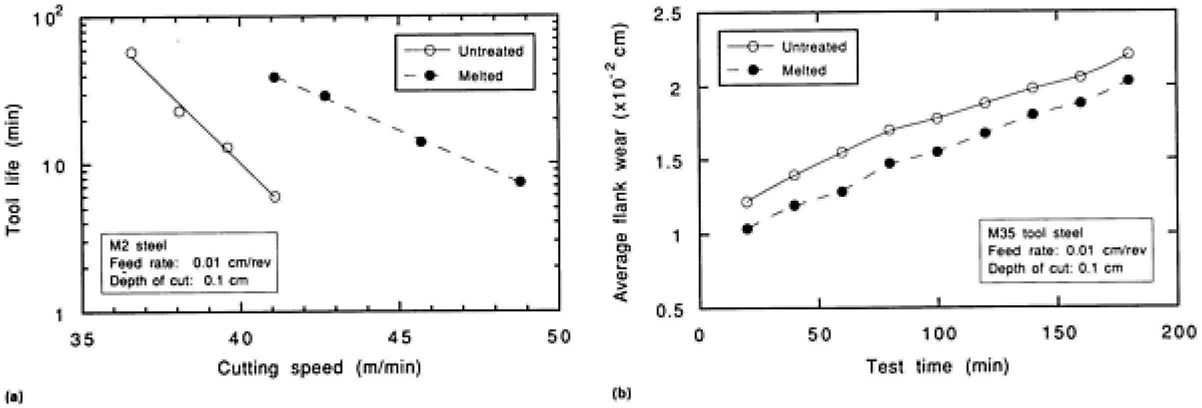

Fig. 8 Tool life of conventionally heat-treated and laser-melted tool bits. (a) M2 tool steel. (b) M35 tool steel. Source: Ref 31

Coquerelle and Fachinetti (Ref 32) laser melted Al-Si alloys and found that the resulting reduction in dendrite size and Si particle size improved wear resistance. Using a pin-on-disk wear measurement technique, the wear volume was reduced 10-fold for a hypoeutectic alloy. The wear rate decreased with increasing silicon content as long as the silicon particle size was less than 2 μm (80 μin.).

Applications of Laser Melting. The benefits of laser melting cast irons are the achievement of very high hardness and wear resistance on a relatively cheap material that is tough in the bulk, in the case of ductile iron, and easy to shape. Tool steels can also be laser surface melted to give very high hardness and wear resistance properties. Although several studies on specific alloys have been performed, there are very few commercial applications for laser surface melting to improve wear resistance. However, during laser transformation hardening, a very thin surface layer is sometimes melted, and the tribological benefits of laser melting are realized in the laser-hardening examples.

Bergmann (Ref 22) describes the application of laser melting to a cast iron rocker arm and camshaft. The laser-melted components achieved a lifetime that was four times better than was achieved by melting using gas tungsten are welding. A German automotive manufacturer routinely uses laser melting to harden camshafts.

Laser Alloying

Processing. A technique of localized alloy formation is laser surface melting with the simultaneous, controlled addition of alloying elements. These alloying elements diffuse rapidly into the melt pool, and the desired depth of alloying can be obtained in a short period of time. By this means, a desired alloy chemistry and microstructure can be generated on the sample surface; the degree of microstructural refinement will depend on the solidification rate. The surface of a low-cost alloy, such as mild steel, can be selectively alloyed to enhance properties, such as resistance to wear, in such a way that only the locally modified surface possesses properties typical of tribological alloys. This results in substantial cost savings, and reduces the dependence on strategic materials. Typical processing parameters for laser alloying are a power density from 10 to 3000 MW/m^2 (6.5 to 1935 kW/in.^{2}) and an interaction time from 0.01 to 1 s. An inert shielding gas is normally used.

One method of alloying is to apply appropriate mixtures of powders on the sample surface, either by spraying the powder mixture suspended in alcohol to form a loosely packed coating, or by coating a slurry suspended in organic binders (Ref 33). The use of metal powders in laser alloying is the least expensive, but, with appropriate process modifications, alloys in the form of rods, wires, ribbons, and sheets can also be added. Because of inconsistency in coating application and possible loss during processing, the composition of the surface alloy may not reflect that of the applied alloying elements.

Powders that are added in controlled quantities using powder feeders with electronic metering can reduce this problem. Powders usually range from 10 to 50 μm (0.4 to 2 mils); the finer size facilities dissolution and alloying. Typically, the powder flow rate is from 0.005 to 0.1 cm^3/s (0.0003 to 0.006 in. ^{3}/s), particle velocity is from 1 to 5 m/s (3.3 to 16.4 ft/s), and carrier gas velocity is from 3 to 10 m/s (10 to 33 ft/s). Whether preplaced or fed, the powder increases the coupling coefficient of the surface, thereby avoiding the need for special absorptive coatings.

During surface alloying, temperature gradients form in the melt pool, which, along with the addition of alloying elements, influences the surface tension. Convection currents are established as a result of the surface tension gradients, and can cause variations in concentration. If the laser beam is oscillated, the melt spreads out over a wider region and, because the beam sweeps the same area several times, a potentially beneficial mixing action can occur. Any alloy concentration gradients that may have formed initially are thus diminished. If the melt pass is made with a very rapid sample translation rate that is greater than 50 mm/s (2 in./s), then inhomogeneities in the microstructure can result, but the high quench rate ensure minimal segregation. The rapid quench also facilitates alloying with hard-to-alloy elements, such as iron, chromium, carbon, and manganese. Examples of laser alloying are cast irons with chromium, silicon, and carbon; steels with chromium, molybdenum, boron, and nickel; stainless steels with carbon; aluminum with silicon, carbon, nitrogen, and iron; and superalloys with chromium.

Another method of laser alloying is gas reaction, for which a shielding gas of appropriate composition is chosen (Ref 34). For the nitriding of titanium alloys, a dilute (10 to 20%) mixture of N_2 in argon is used as the reactive gas. The extent of nitriding depends on the partial pressure of N_2 in the atmosphere, which is determined by the law of mass action, and the temperature, which depends on the laser power density. Alloys of titanium can be carburized by using a methane/argon mixture, and carbonitrided by using a methane/N_2 mixture.

Folkes *et al.* (Ref 25) nitrided titanium alloys by blowing N_2 with a flow rate of 100 to 250 cm^3/s (6 to 15 $in.^3/s$) onto the melted surface. Influenced by the mixing effects derived from surface tension forces and from the impingement of the N_2 jet on the surface, nitrogen was uniformly distributed and TiN formed throughout the melt zone. The authors also carbonitrided titanium alloys by applying a carbon-base paint over the surface and then laser melting in the presence of a N_2 gas jet.

Examples of Laser-Alloyed Surface Microstructures. With laser alloying, a microstructure that strengthens the surface is produced to develop resistance to wear. Surface alloying of AISI 1018 steel with carbon and chromium produces stable carbides, such as M_7C_3 and M_3C, in austenitic, pearlitic, or martensitic matrices (Ref 33). The microhardness of these carbides is from 1100 to 1200 HK, and, when uniformly dispersed in a pearlitic or martensitic matrix, results in an improved resistance to abrasive and adhesive wear. With a 16% addition of chromium, the microstructure of laser-alloyed 1018 steel is martensitic, with small islands of ferrite, as shown in Fig. 9(a). With additions of 43% Cr and 4.4% C, the microstructure consists of hexagonal-shaped M_7C_3 carbides, as shown in Fig. 9(b).

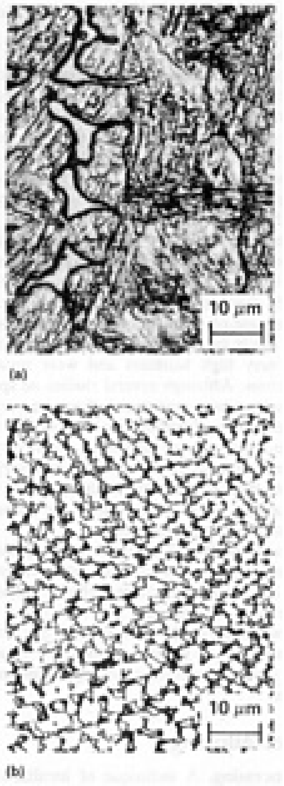

Fig. 9 Microstructures of laser-alloyed 1018 steel. (a) Addition of 16% Cr. (b) Addition of 43% Cr and 4.4% C. Source: Ref 33

Marsden *et al.* (Ref 35) found that laser melting of graphite-coated stainless steels produced dendritic austenite and interdendritic carbides with a microhardness of 600 HV, whereas carbon-powder-injected microstructures contained martensitic cells, with segregated carbon and chromium forming a small amount of eutectic in the intercellular regions. With increasing carbon content, the hardness was increased to 1500 HV, because of the increase in carbide volume.

The reactivity of titanium makes its alloys ideal targets for laser alloying by gas reaction. TiC, TiN, and carbonitrides form as dendrites in a titanium matrix throughout the melted area. The matrix is α' in Ti-6Al-4V (Ref 34) and β in Ti-15Mo (Ref 25). Laser gas alloying can also be used to increase the carbon content of low-carbon steels, and to produce ledeburite structures on steels.

Wear Behavior of Laser-Alloyed Surfaces. Yu and Quan (Ref 36) laser alloyed steel with carbon, nitrogen, and boron and found that the abrasive wear resistance improved 13 times, compared to that of unalloyed steel. This improvement was due to the hardening caused by a uniform dispersion of nitrides, carbides, and borides in a fine dendritic ferritic matrix. Rieker *et al.* (Ref 37) laser alloyed a free-machining ferritic stainless steel with various combinations of

molybdenum and boron by applying the elements as paint. For chemical and structural homogeneity, a second remelting was done. As shown in Fig. 10, the wear behavior improved under all alloying conditions. A microcrystalline ferritic structure with a dispersion of boride particles was responsible for the improved abrasive wear resistance.

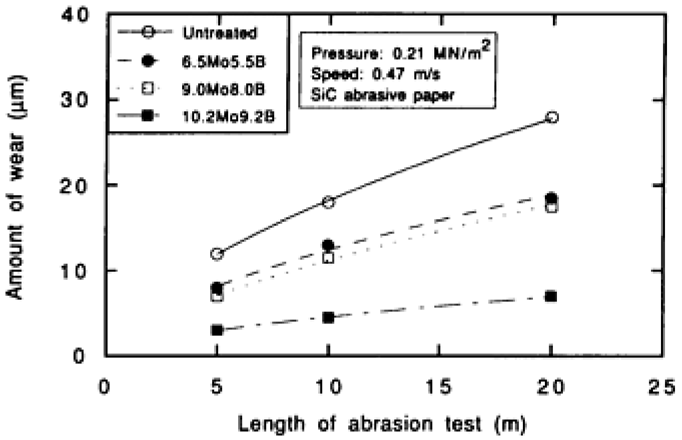

Fig. 10 Wear behavior of untreated and laser-alloyed ferritic stainless steel. Source: Ref 37

Using a dry-sand-rubber wheel abrasion test, Tan and Doong (Ref 38) found that when AISI 1018 steel was layer alloyed with chromium, the abrasion resistance improved because of the formation of a martensite-ferrite structure. Xiaoping *et al.* (Ref 39) laser alloyed low-carbon steel with two Co-Cr-W combinations. With 17Co7Cr3W (815 HV), abrasive wear resistance was better, whereas with 52Co22Cr9W (625 HV), corrosive wear resistance was better. In the former, martensite formed, whereas in the latter, a mixture of γ-Co and $Cr_{23}C_6$ formed.

Huntz *et al.* (Ref 40) improved the pin-on-disk wear behavior of 70Ni30Cr by laser melting the alloy that was precoated with carbon. The formation of a variety of chromium-rich carbides in a γ-phase solid solution contributed to the improvement in wear resistance.

Mordike (Ref 34) reported improved rolling and adhesive wear resistance of titanium by laser gas alloying. The increased surface hardness improved resistance to penetration and, thus, the resistance to plowing wear and erosion.

Applications of Laser Alloying. Laser alloying has been primarily applied to improved corrosion resistance. A very common technique is to alloy steels with chromium. The only examples of laser alloying to improve wear resistance are exhaust valves fabricated by Fiat Research Laboratory.

Laser Cladding

Processing. In laser cladding, a necessarily different material is fused to the substrate surface with minimal dilution. The cladding has a microstructure and properties that are entirely different from those of the substrate. Lasers enable the cladding of high-melting-point alloys over low-melting-point workpieces (Ref 33). Cobalt-, nickel-, and iron-base hardfacing alloys are the usual cladding materials used for metal-to-metal contact, impact, erosion, and abrasion wear resistance.

Cladding material selection depends on its metallurgical compatibility with the substrate material. Alloys that form brittle intermetallic phases with the substrate are undesirable. For example, cobalt forms harmful intermetallics with titanium, and cobalt-base cladding alloys would be unsuitable on titanium alloy substrates.

The cladding alloy is melted by a laser beam and allowed to spread freely and freeze over the substrate. The beam also melts a very thin layer of the substrate, which combines with the liquid cladding to the least extent necessary and solidifies to form a strong metallurgical bond. A good fusion bond can be achieved with a dilution zone that is only from 10 to 20 μm (0.4 to 0.8 mil) thick.

The clad alloy can be in several forms, examples of which are a prealloyed powder that is applied to the sample surface with or without a binder, a self-fluxing powder that is flame sprayed, a hard-facing alloy that is plasma sprayed, or a chip that is preplaced. Laser consolidation of these coatings results in densification and smoothening, eliminates channels to the substrate, improves the bonding between coating and substrate, and reduces porosity, all of which contribute to the strength and integrity of the clad layer. Processing parameters for laser cladding are a power density that ranges from 10 to 1000 MW/m^2 (6.5 to 645 $kW/in.^2$) and an interaction time from 0.1 to 1 s. The shielding gas could be any of the inert gases or a combination of gases, such as He/Ar and H_2/Ar.

It is sometimes difficult to keep preplaced powder in place as it is melted by the laser beam. The external addition of powder avoids this problem. The clad material can be gravity-fed just ahead of the beam spot, so that as the sample translates, the laser beam melts and fuses the powder to the workpiece.

With the help of a suitable carrier gas, the powder can also be blown into the laser-melted pool. In this case, the melt pool is mostly clad material, with the leading edge incorporating a small portion of the substrate surface. Particle size usually ranges from 45 to 150 μm (1.8 to 6 mils), with the larger size helping to minimize alloying.

The amount of dilution and clad thickness are controlled by the interaction time and the powder flow flux. Desirable dilutions are from 3 to 8%. Clad thickness can be varied from 0.05 to 4 mm (2 to 155 mils). The optimum powder flow flux is one that gives minimum dilution and maximum deposition (Ref 1). The lowest particle velocity needed to uniformly convey the powder to the melt pool is desirable to minimize losses from the molten pool. The powder delivery nozzle is positioned in such a manner as to flood the entire melt pool with powder. The feeding angle is generally from 35 to 45° to the horizontal, and the feed tube, which typically has a 3 mm (0.12 in.) diam, is positioned from 10 to 12 mm (0.4 to 0.5 in.) from the substrate. Typically, the powder flow rate is from 0.005 to 0.1 cm^3/s (0.0003 to 0.006 $in.^3/s$), particle velocity is from 1 to 2 m/s (3.3 to 6.6 ft/s), and carrier gas velocity is from 3 to 7 m/s (10 to 23 ft/s). Uniform feeding of the powder ensures uniform clad layers. Unlike plasma-sprayed coatings, porosity and unmelted powder particles are almost never observed within a laser-clad layer.

The shape of the cladding can be controlled within certain limits, the most preferred shape being one with an obtuse angle to the substrate. Multiple clad tracks produced by overlapping such a clad layer will have a good surface finish and be porosity-free. Cladding is commonly achieved by relatively large "doughnut-shaped" beams, or by somewhat focused beams that are oscillated. These ensure a desirable clad profile. Clad material can also be added in rod, wire, or sheet form, but special procedures are needed because of reflectivity problems.

Thermal stresses in the cladding can cause harmful cracking, but this can be eliminated by an appropriate preheating practice. Low power densities, large beam diameters, and slow sample translation rates tend to produce crack-free clad layers.

Ayers and Gnanamuthu (Ref 33) give several examples of laser cladding for improved wear resistance, such as Tribaloy T-800 on powder-coated ASTM A 387 steel; Haynes Stellite alloy No. 1 cast rods placed on AISI 4815 steel; and a mixture of WC and Fe powder applied without binder on AISI 1018 steel.

In addition to stainless steel on mild steel, Steen (Ref 1) has reported successful laser cladding of nickel, bronze, Fe-B, and Stellite SF6 on mild steel; chromium on titanium; stainless on aluminum; mild steel on stainless, and stellite on brass. Other examples of laser cladding are AISI 1016 steel clad with a mixture of chromium, manganese, and carbon powders (Ref 41) and gray cast iron clad with a powder-fed mixture of molybdenum, Cr_2C_3, chromium, nickel, and silicon (Ref 42).

Examples of Laser-Clad Layer Microstructures. The key to improved wear resistance is the presence of hard phase distributions in the laser-clad microstructures. The wear resistance of Tribaloy is attributed to the presence of hard Laves intermetallic phases surrounded by solid solution and a eutectic matrix (Ref 33). In T-800 alloy, the Laves phases make up nearly 50 vol% of the microstructure (Fig. 11a), and the cladding has an average microhardness of 690 HK. Stellite alloy No. 1 contains M_7C_3 and M_6C carbides finely dispersed in an austenitic cobalt matrix (Fig. 11b), and has a microhardness of 730 HV. Microstructural analysis of the WC-Fe mixture revealed a distinct region on the WC particles, which formed because of interaction with the liquid iron. Microhardness of the WC particles was 1100 HK, and that of the surrounding matrix was 870 HK.

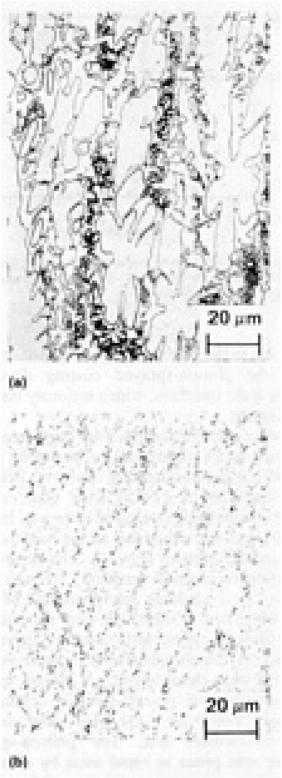

Fig. 11 Examples of laser-clad microstructures. (a) Tribaloy T-800 alloy on ASTM A 387 steel. (b) Haynes Stellite alloy No. 1 on AISI 4815 steel. Source: Ref 33

The Fe-Cr-Mn-C cladding of Mazumder and Singh (Ref 41) had a microstructural consisting of M_7C_3 and M_6C type carbides in a ferritic matrix, a solid solubility extension of chromium in ferrite by 50%, and a microhardness of 550 HV. The molybdenum-clad coating on gray iron of Belmondo and Castagna (Ref 42) consisted of molybdenum dendrites surrounded by a Cr-Ni matrix containing Cr_2C_3, which had a microhardness of 900 HV.

Wear Behavior of Laser-Clad Layers. Mazumder and Singh (Ref 41) found that the Fe-Cr-Mn-C cladding on AISI 1016 steel resulted in tribological properties that were superior to Stellite 6. The width of the wear scar was reduced from 3.5 mm (0.14 in.) in the base alloy to about 0.6 mm (0.02 in.) in the laser cladding. Under the same test conditions, Stellite 6, a common hardfacing alloy, developed a wear scar which of 1.4 mm (0.06 in.).

Abbas *et al.* (Ref 43) laser clad a mild steel with Stellite 6, Alloy 4815, and their composites with SiC by using pneumatic powder delivery. Wear tests, conducted by grinding the samples against a revolving alumina disk, showed that the composite clad samples had the best abrasive wear resistance (Fig. 12).

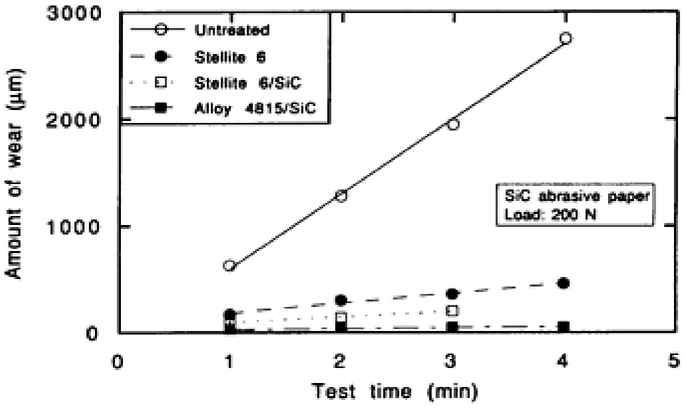

Fig. 12 Abrasive wear behavior of mild steel laser clad with Stellite 6, Stellite 6/SiC, and Alloy 4815/SiC. Source: Ref 43

Belmondo and Castagna (Ref 42) performed wear tests on the Mo-Cr_2C_3 clad cast iron samples using a reciprocating motion testing machine. When compared with plasma-sprayed coatings of similar composition, the performance of laser-clad coatings was far superior under all testing conditions, especially at the highest pressures. With a load of 25 MPa (3.6 ksi) and slider roughness of 0.3 μm (12 μin.), the wear loss in the laser sample was 0.4 mg (1.4×10^{-5} oz), compared to 1.3 mg (4.6×10^{-5} oz) in the plasma-sprayed sample. In addition, the plasma-sprayed coating developed cracks at the interface, which seriously impaired its integrity.

Molian and Hualun (Ref 44) performed pin-on-block reciprocating sliding wear tests on Ti-6Al-4V alloy substrate laser clad with BN, both with and without a NiCrCoA1Y addition, and found that the wear resistance improved from 10 to 200 times more than that of age-hardened and laser-melted samples (Fig. 13). The presence of solidification reaction products, TiN and TiB_2, resulted in a cladding microhardness of 1600 HV, which led to improved wear resistance by preventing ploughing and reducing friction.

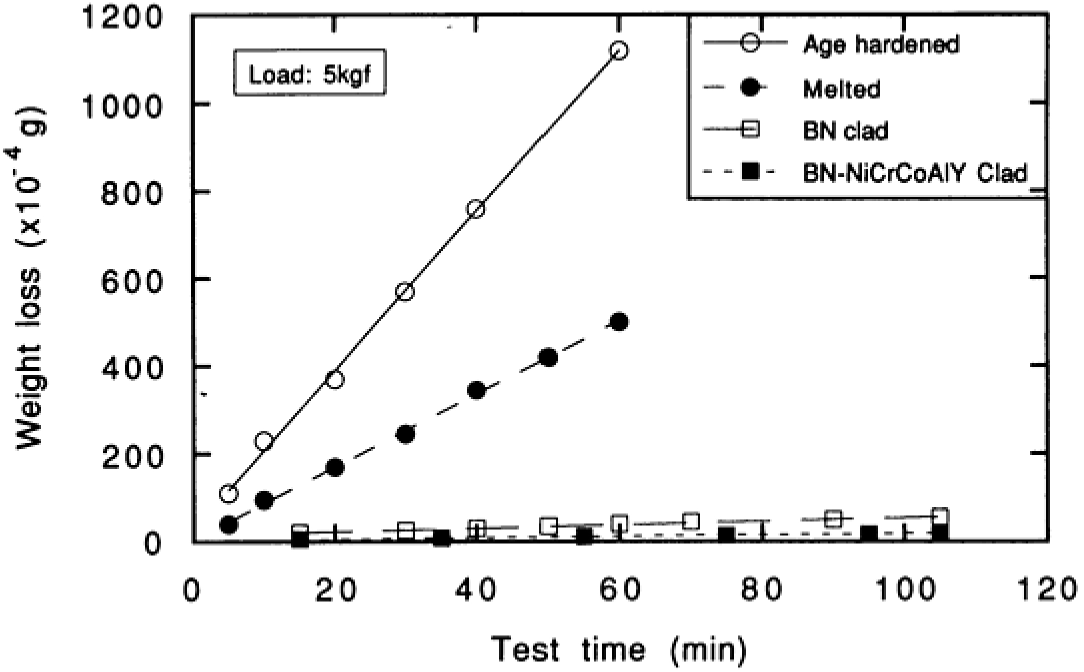

Fig. 13 Sliding wear behavior of laser-clad Ti-6Al-4V alloy. Source: Ref 44

Boas and Bamberger (Ref 45) determined the abrasive wear characteristics of plasma-sprayed and laser-melted plasma-sprayed coatings of Tribaloy T-400 on AISI 4130 steel using a block-on-cylinder test. The plasma-sprayed coating was prone to rapid wear by delamination, whereas laser consolidation of the plasma coating removed flaws, such as porosity and microfissures, and generated an adherent wear-resistant layer. Figure 14 demonstrates the improvement in wear after laser consolidation of the plasma coating. For comparison, results on a hard D2 steel are also given.

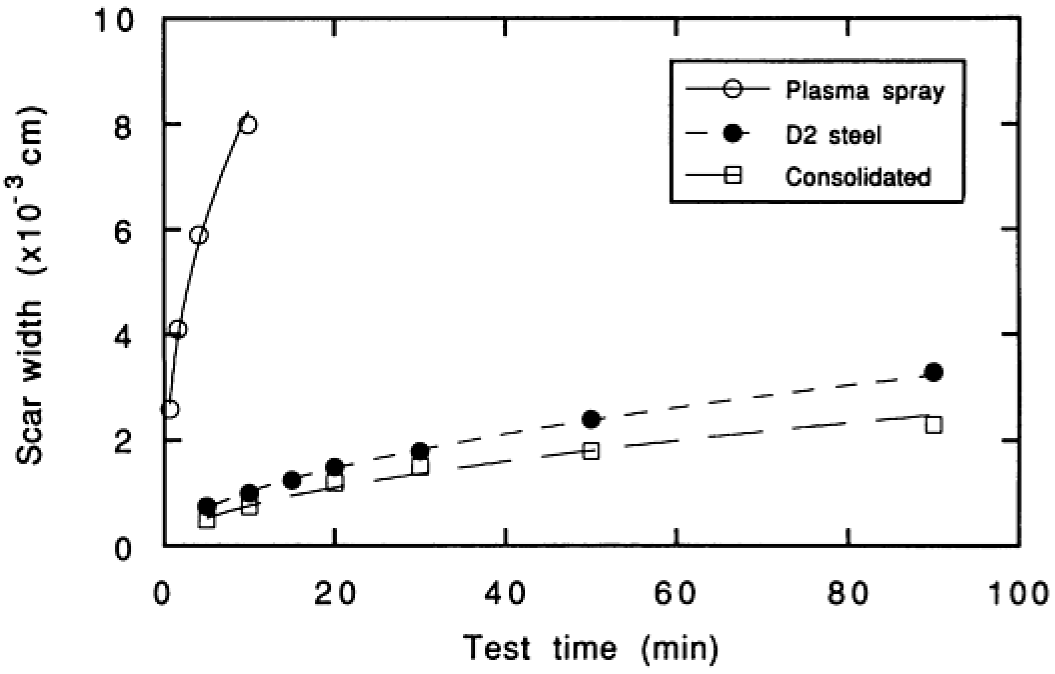

Fig. 14 Wear scar growth curves of plasma-coated 4130 steel before and after laser consolidation. Source: Ref 45

Laser-Cladding Applications. Because one of the primary goals of laser cladding is to improve the tribological properties of components, several applications have been found for the technique. Some of them are in the exploratory stage, others are in the pilot-plant stage, and a few have reached the production stage.

Bruck (Ref 46) demonstrated cladding within a confined space by coating the inside surface of small-bore pipes (inside diameter of 50 to 100 mm, or 2 to 4 in., and length of 0.3 to 1.2 m, or 1 to 4 ft), as shown in Fig. 15. An oscillating mirror placed in the pipe formed a 12.5 mm (0.5 in.) wide melt pass, into which the clad alloy powder was fed. The pipe was rotated and translated to cover the entire inner surface. Previously, chrome plating was used, but the laser technique appreciably improved galling resistance. Using suitable cooling techniques, the pipe temperature was maintained below 500 °C (930 °F) to avoid deterioration of the core properties, as well as distortion.

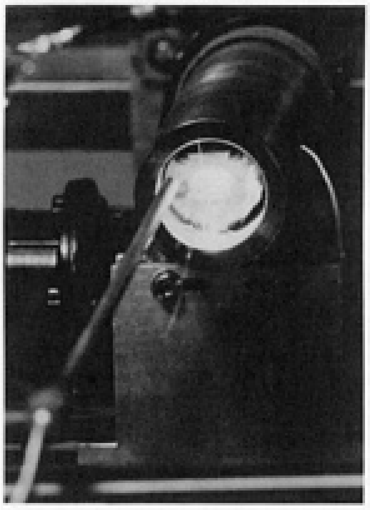

Fig. 15 Laser cladding of small-bore pipes. Source: Ref 46

La Rocca (Ref 19) describes laser cladding of exhaust valves with stellite at an Italian automotive manufacturer. The stellite powder was fed into the laser melt pool. The laser-clad material was superior to gas tungsten arc welded material in terms of thickness uniformity and uniform microstructure and elemental distributions, and had better adhesion. Powder utilization also was better (30% that of gas tungsten arc welding), and over-metal removal was reduced by 10 to 15%. One British automotive manufacturer uses production-stage laser cladding of a nickel-alloy turbine blade shroud interlock by powder feeding either Tribaloy or Nimonics (Ref 47). Previously, a manual arc melting technique was used. Laser cladding reduced cladding time from 14 min to 75 s, improved productivity and quality, reduced cost by 85%, and reduced powder consumption by 50%. Table 2 lists components that are laser clad for commercial applications.

Table 2 Component, cladding alloy, and cladding technique

Component	Clad alloy	Cladding technique	Company	Ref
Gate and seat of steel valves for oil-field, geothermal, and nuclear energy production, and chemical processing	Stellite 6	Powder feed	W-K-M Div. of Joy Mfg., Houston, TX	48
Diesel engine valve	Stellite SF6	Preplaced powder paste	Cabot Corp., Kokomo, IN	49
Gate valve seat	Deloro 60	Preplaced powder paste	Cabot Corp., Kokomo, IN	49
Gas turbine blade "Z" notch	Co-base alloy	Powder feed	Quantum Laser, Edison, NJ	50
Leading edge of turbine blades	Co-base alloy	Powder feed	Quantum Laser, Edison, NJ	50
Pump bushings and impellers	Co-base alloy	Powder feed	Quantum Laser, Edison, NJ	51
Engine valve bases	Ni-Cr alloy	Powder feed	Quantum Laser, Edison, NJ	51
Oil-field valve gates	WC and Co alloy	Powder feed	Quantum Laser, Edison, NJ	51
Tractor bushings	Stellite 6	Powder feed	Quantum Laser, Edison, NJ	51
Turbine blades, pump valve seats	Stellite, Colmoloy, blended powder	Preplaced beds, gravity feed	Westinghouse, Pittsburgh, PA	52
Valve stem, valve seat, aluminum block	CrC_2, Cr, Ni, Mo/cast Fe	Preplaced powder	Fiat, Turin, Italy	52
Off-shore drilling and production parts, valve components, boiler firewall	Stellite, Colmonoy, alloys/carbides	Powder feed	Combustion Eng., OH	52
Aerospace components	Stellite, Tribaloy	Powder feed	Rockwell Int., CA	52

Turbine blade shroud interlocks	PWA 694, Nimonics	Preplaced chip	Pratt & Whitney, West Palm Beach, FL	52
Turbine blade "Z" notch	Hardfacing	Powder feed	United Technol., E. Hartford, CT	53
Swivel joints, petroleum valves	Hardfacing	Powder feed	Spectra Physics, San Jose, CA	53
Gas engine turbine blades	Hardfacing	Powder feed	General Electric, SC	54

Laser Melt/Particle Injection

Processing. Laser melt/particle injection produces an *in situ,* metal-matrix/particulate composite surface layer by mixing, but not melting, the second phase with the substrate. The particulate material is injected with sufficient velocity as a spray into the melt pool formed by the laser beam. If the second phase is hard, such as a carbide, the injected layer can be made to resist wear.

Figure 16 depicts the laser injection process. An oscillating CW CO_2 laser beam produces a shallow melt pool on a substrate, into which are injected powder particles via a nearby nozzle. As the sample translates, an injected layer forms on the surface. By varying the amplitude of oscillation, melt widths ranging from 3 to 20 mm (0.12 to 0.8 in.) are possible (Ref 55). Processing conditions for laser melt/particle injection are a power density from 10 to 3000 MW/m^2 (6.45 to 1935 $kW/in.^2$) and an interaction time from 0.1 to 1 s. Any inert shielding gas is normally used.

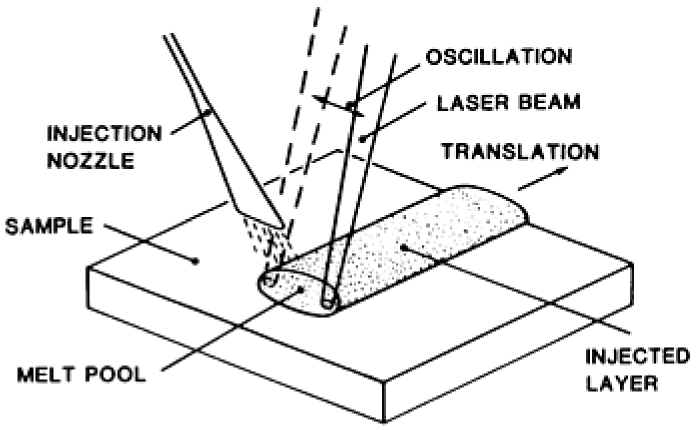

Fig. 16 Laser melt/particle injection process

The particles are propelled by pressurized helium gas. The pressure depends on the particle size and the relative densities of the powder and the molten substrate. Larger and heavier particles require lower gas pressures. Typically, powder flow rates are from 0.1 to 0.5 cm^3/s (0.006 to 0.03 $in.^3/s$) and particle velocities are a few m/s. Carrier gas pressures typically range from 50 to 120 kPa (7.3 to 17.4 psi). The carrier gas also serves as a cover gas and keeps the particles relatively cool, preventing them from melting or fusing. Particle sizes range from 45 to 150 μm (1.8 to 6 mils). Finer particles tend to either fuse or dissolve in the melt, whereas coarser particles do not flow easily.

The injection nozzle, usually made of copper, is inclined at 60° to the horizontal and is positioned from 10 to 20 mm (0.4 to 0.8 in.) away from the sample. Its slotted opening is designed to produce a rectangular spray that is of the same size as the melt pool, to ensure that most of the powder is incorporated into the melt.

Although minimum interaction between the carbide phase and the melt is desired, some dissolution does occur. It was found that the degree of carbide dissolution, as well as other physical characteristics of the injected layer, such as penetration depth, mounding, and carbide volume, could be reasonably controlled. Variations in these characteristics, as well as hardness, with laser power and powder feed rate, are determined for Ti-6Al-4V alloy injected with TiC (Fig. 17) (Ref 56). The carbide volume can be varied from 15% to a limit of 60%. For improved wear resistance, higher carbide volumes are desirable, but the conditions that produce increased carbide volume also increase dissolution. An estimation

of the degree of carbide dissolution is given by matrix microhardness. As the trends in Fig. 17 show, matrix microhardness is higher when the carbide volume is greater.

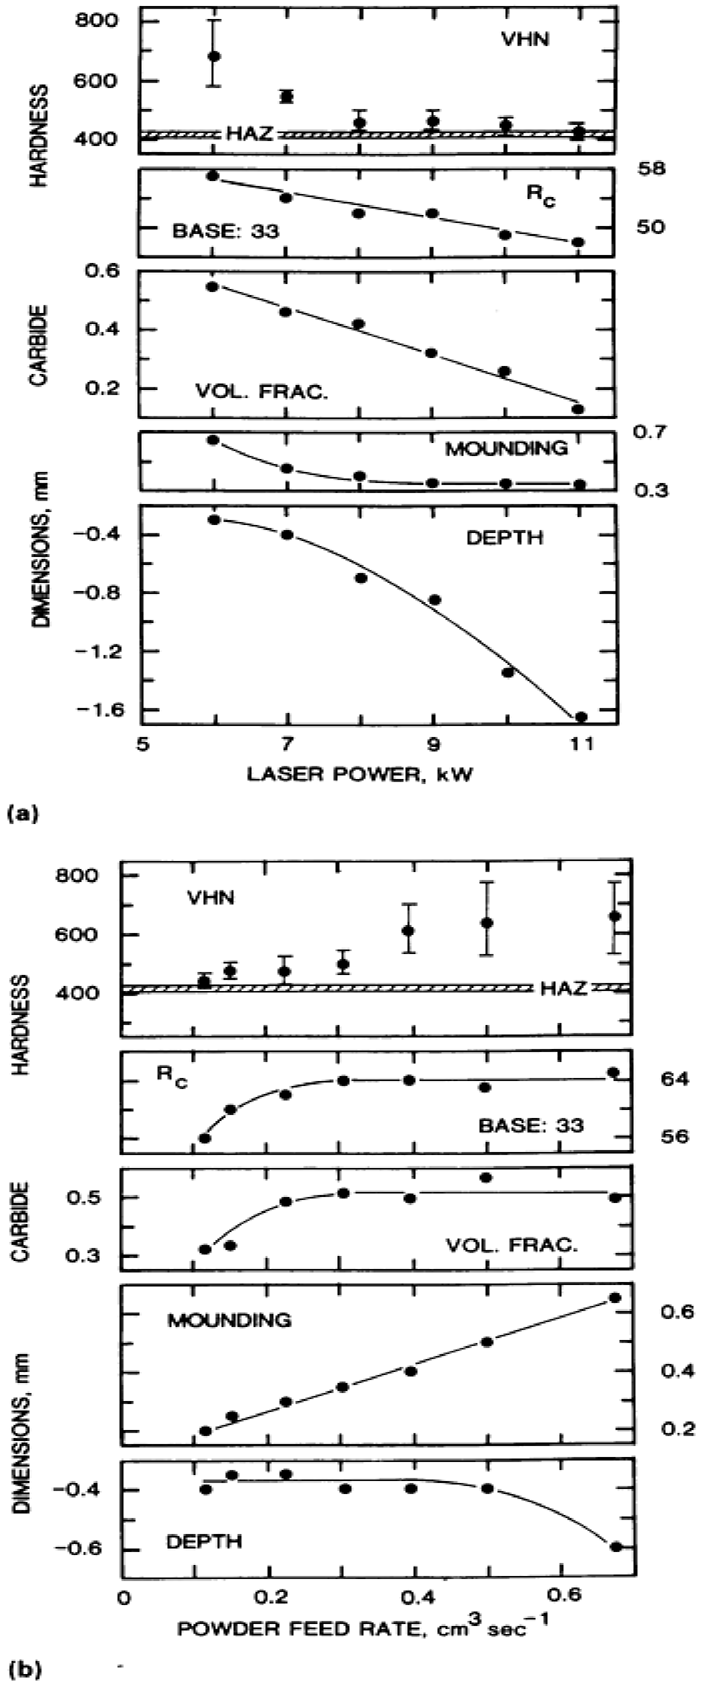

Fig. 17 Effect of processing parameters on injected layer characteristics in Ti-6Al-4V injected with TiC. (a) Laser power. (b) Powder feed rate. Source: Ref 56

Initial work on laser melt/particle injection was done on low-density/high-strength aluminum and titanium alloys, for which few surface-hardening methods exist. Some of the alloy/particulate systems that have been investigated are 5052 Al/TiC, Al bronze/TiC, Ti-6Al-4V/TiC, Ti-6Al-4V/WC, 304 stainless/TiC, 4340 tool/TiC, Inconel 625/TiC, and Inconel 625/WC (Ref 57).

Microstructures of Laser Melt/Particle-Injected Layers. The injected layer is a composite of particles surrounded by a metal matrix. It is desirable that the only surface modification be the presence of the particulate phase, and that the surrounding metal should remain unchanged and retain most of the substrate properties, such as corrosion resistance and toughness. Figure 18 shows the cross-sectional view of a WC injected layer on Inconel 625 alloy substrate. The top surface is rough, but is free of deep channels. The light grains are the WC particles, which are surrounded by the dark Inconel. The carbides are uniformly distributed throughout the injected layer and occupy about 50% of the total volume. Because the matrix phase is essentially made of the same material as the substrate, there is chemical continuity across the interface and a strong metallurgical bond.

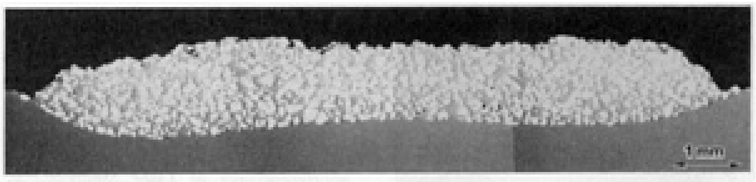

Fig. 18 Cross section of Inconel 625 alloy injected with WC

Carbide dissolution products formed during solidification can influence the matrix microstructure. The carbide particles sometimes develop a perturbed or scalloped, highly alloyed interface with the metal matrix. Eutectic and dendritic carbides are some of the dissolution products that appear within the matrix (Ref 58). Figure 19 shows examples of some of the dissolution products. Besides influencing properties such as microhardness and friction wear, these resolidification products can cause matrix embrittlement and microcracking, although with suitable preheating, cracking can be eliminated (Ref 59).

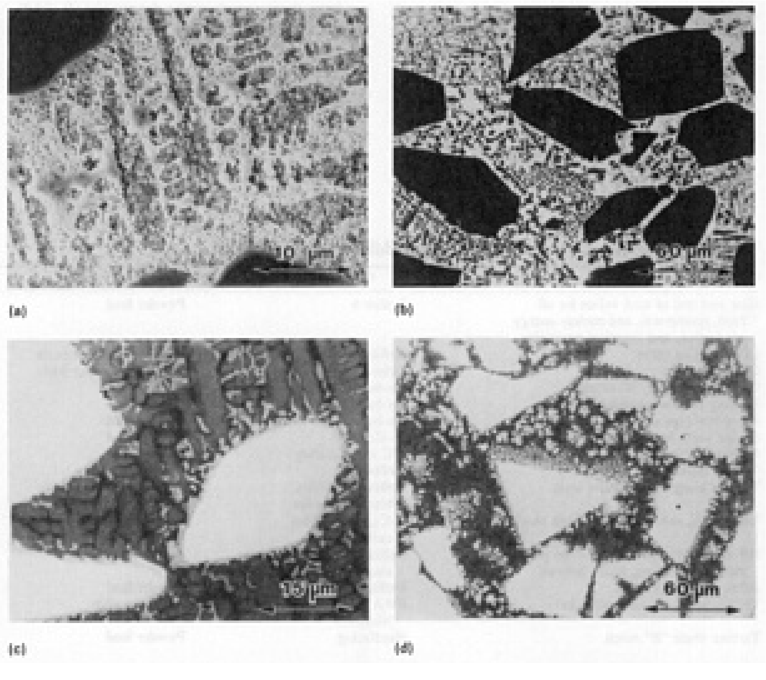

Fig. 19 Carbide morphological changes and matrix resolidification products as a result of carbide phase dissolution in Inconel 625 alloy. (a) Injected with TiC, eutectic carbides. (b) Injected with TiC, dendritic carbides. (c) Injected with WC, eutectic carbides. (d) Injected with WC, dendritic carbides

In order to retain some of the substrate properties in the modified surface, it is important to keep carbide dissolution to a minimum. Some of the matrix microstructural changes are inevitable. Depending on the base alloy, melting and rapid solidification can result in microstructural refinement, formation of solid solutions, phase transformations, and precipitation. These microstructural modifications, along with the dissolution products, can harden the matrix by various mechanisms. Carbide dissolution products harden the matrix by a dispersion-hardening mechanism. This effect was observed in stainless steel, tool steel, Inconel, and titanium alloys. Transformation hardening comes into play when martensite forms in steels and titanium alloys. In tool steels, precipitation hardening also plays a role, and in aluminum bronze, microstructural refinement results in modest hardening (Ref 57).

Wear Behavior of Particle-Injected Surface Layers. On a macroscopic scale, hardening of particle-injected alloys is due to plastic flow inhibition by the injected phase. The relative increase in macrohardness of the composite surface is from 1.1 to 2.6 times, depending on the alloy (Ref 57). On a microscopic scale, hardening of the metal matrix varies with the type of alloy and has been found to affect friction wear behavior (Ref 60).

Friction wear was evaluated using a balt-on-surface test, which measures the coefficient of kinematic friction, μ_k, between a hard steel ball and a polished sample surface. A pressure of 1 N (0.22 lbf) and a slide velocity of 0.0001 m/s (0.02 ft/min) were used. This test is sensitive to minute changes in microstructure. For untreated Inconel 625, μ_k was about 0.7. Particle-injected Inconel 625 had a μ_k that ranged from 0.15 to 0.20 after the first slide, which increased to a range from 0.3 to 0.4 for WC and 0.4 to 0.45 for TiC after several slides (Fig. 20). The wear scar was hardly evident in the optical microscope and there was very little abrasive damage. Although μ_k increased with number of slides, it was not due to continuous wear of the sample surface. Rather, it was due to formation of wear debris.

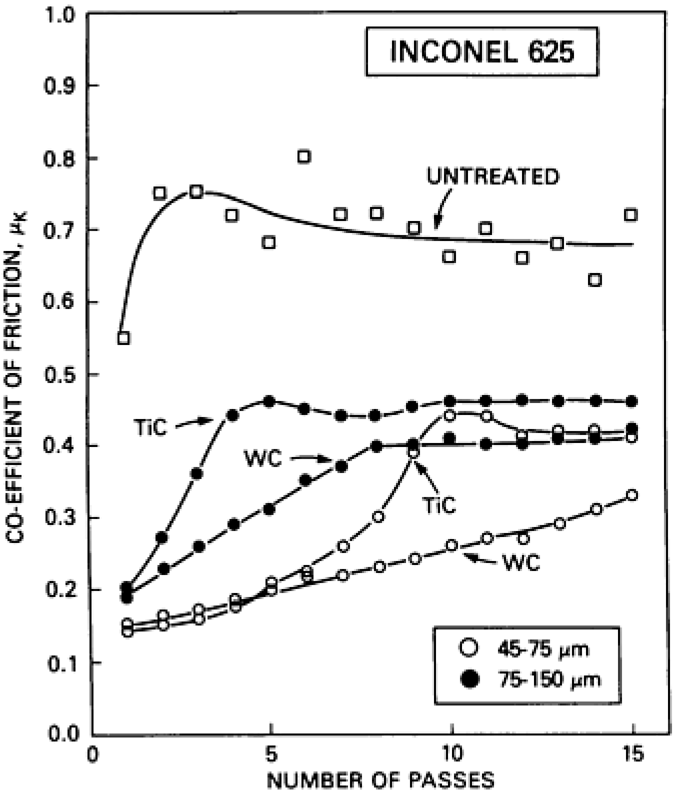

Fig. 20 Coefficient of friction as a function of number of slides in untreated and particle-injected Inconel 625. Source: Ref 60

The wear mechanism was different for the two carbides. With WC injection, the carbide and the harder (600 to 650 HV) metal matrix were strong enough to cause the slider to wear, and the wear debris was mostly that from the steel ball. With TiC injection, the wear debris was a mixture of material from the steel ball and from the softer (400 to 500 HV) metal matrix (Ref 60).

From dry sand/rubber wheel tests done on aluminum- and titanium-base alloys injected with TiC, it was found that the wear volume decreased rapidly with modest volumes of the carbide phase. For aluminum, the reduction is from 0.18 to 0.28 cm^3 (0.01 to 0.02 $in.^3$) to 0.02 to 0.025 cm^3 (0.0012 to 0.0015 $in.^3$). For titanium, it is from 0.06 to 0.065 cm^3 (0.0037 to 0.0040 $in.^3$) to 0.01 cm^3 (0.0006 $in.^3$) (Fig. 21) (Ref 61). Examination of the worn surface showed that the softer metal matrix eroded, but that the hard carbide particles prevented further erosion of the surface. The abrasive action did not uproot the carbides from the matrix, but the normally angular carbides appeared slightly rounded, which helped reduce further erosion.

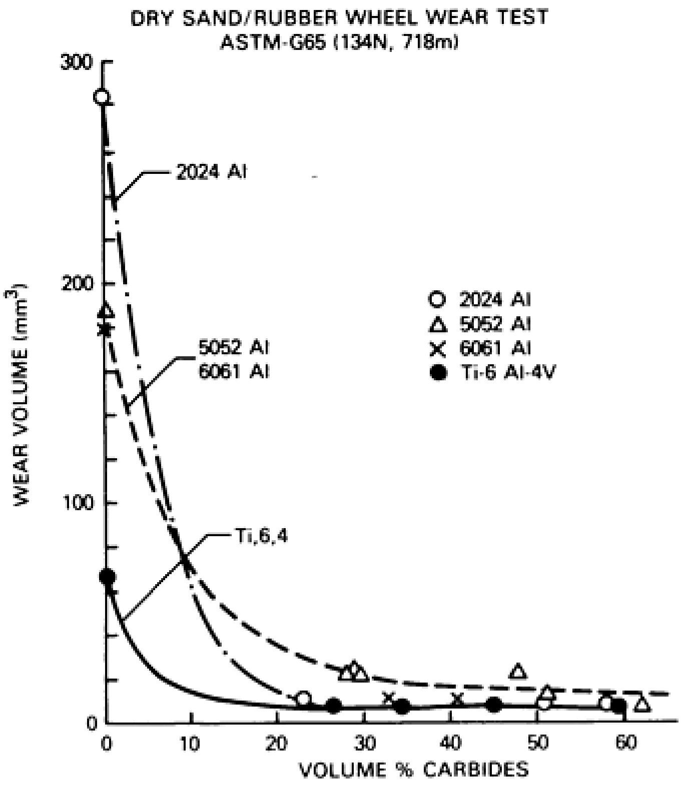

Fig. 21 Reduction in abrasive wear rate with increase in vol% carbide in particle-injected aluminum and titanium alloys. Source: Ref 61

Ayers and Bolster (Ref 62) found that abrasive wear with 3 and 30 μm (120 and 1200 μin.) diamond particles of aluminum and titanium alloy samples was reduced by introducing WC or TiC into their surfaces. The wear resistance of aluminum alloys improved by a factor of 30 in samples containing TiC, whereas for Ti-6Al-4V containing TiC, the improvement was less dramatic (factor of 4).

Applications of Laser Melt/Particle Injection Process. Most of the laser melt/particle injection processing work has involved process optimization, microstructure evaluation, and test sample preparation. One application involved fabrication of wear-resistant surfaces on Inconel alloy shaft seal test rings, such as the one shown in Fig. 22 (Ref 63). The injectant is WC and the circular pass is 127 mm (5 in.) in diameter and 10 mm (0.4 in.) wide. The coverage rate was 130 mm^2/s (0.2 $in.^2/s$). Before testing, the rough surface was ground flat. The seal ring was successfully tested against a graphite mating surface using water as the lubricant.

Carburizing

C.A. Stickels, Environmental Research Institute of Michigan

Introduction

CARBURIZING has been used since ancient times to improve the wear resistance of steel. A low-carbon steel or wrought iron, when heated in the presence of carbonaceous material to a temperature sufficient to form austenite, will dissolve carbon at the surface When quenched to martensite, the carbon-enriched surface layer dramatically increases in hardness. Metalworking artisans learned to combine carburizing with shaping by hot forging to produce tools that retained much of the toughness characteristic of either wrought iron or low-carbon steel, combined with a hard surface to resist wear.

Carburizing is used today to achieve the same combination of toughness and wear resistance (Ref 1). Power-train gears for helicopters, earth-moving equipment, heavy trucks, and passenger cars are all made of carburized steel. Most roller bearings, straight and tapered, are also carburized. The primary advances in carburizing technology in the last 100 years are the development of high-quality alloy steels designed for carburizing and improved processing methods to allow better control over the composition, microstructure, and properties of the carburized case.

The author wishes to thank Dr. David L. Sponseller for reviewing the manuscript.

Carburizing Processes

Gas carburizing is the most-used modern production carburizing technique (Ref 2). Batch or continuous furnaces are used with parts that are either placed on fixtures or loaded in baskets. A carbon-rich furnace atmosphere is provided by an endothermic carrier gas enriched with a hydrocarbon gas, such as methane (natural gas) or propane. Furnaces are often fitted with "sealed oil quenches." Oxidation prior to quenching is prevented by maintaining parts in the carburizing atmosphere during transfer to the quenchant.

Although quenching in oils at temperatures from 50 to 75 °C (120 to 165 °F) is common, many carburized parts are martempered by quenching in oils or molten salts at temperatures from 175 to 200 °C (345 to 390 °F). Because the quench temperature for martempering is above the martensite start temperature of the high-carbon case, the case transforms to martensite during subsequent air cooling.

Other forms of carburizing, described in more detail in Volume 4 of the *ASM Handbook* (1991), include:

- Pack carburizing, where parts are packed in a blend of coke and charcoal with "activators," and then heated in a closed container. This is an old, labor-intensive process, but it is still practiced in tool rooms because facility requirements are minimal.
- Vacuum and plasma carburizing, both of which utilize a vacuum chamber with a partial pressure of hydrocarbon gas as the source of carbon. The gas is ionized in the plasma carburizing process. The prime advantage to these processes is the absence of oxygen in the furnace atmosphere
- Salt bath carburizing, in which the baths contain cyanides, cyanates, or carbon-carbonate blends. These are particularly useful for producing thin carburized cases because the carburizing time can be precisely controlled

Characteristics of Carburized Surfaces

Diffusion of Carbon. Some of the features of carburized cases are due to the fact that they are created by the diffusion of carbon. First, there is a gradual transition in carbon content, as well as a transition in microstructure and mechanical properties, between case and core. As a rule, the deeper the case, the less steep is the slope of the carbon gradient (Fig. 1). The absence of any sharp transition in properties assures excellent adherence of the case.

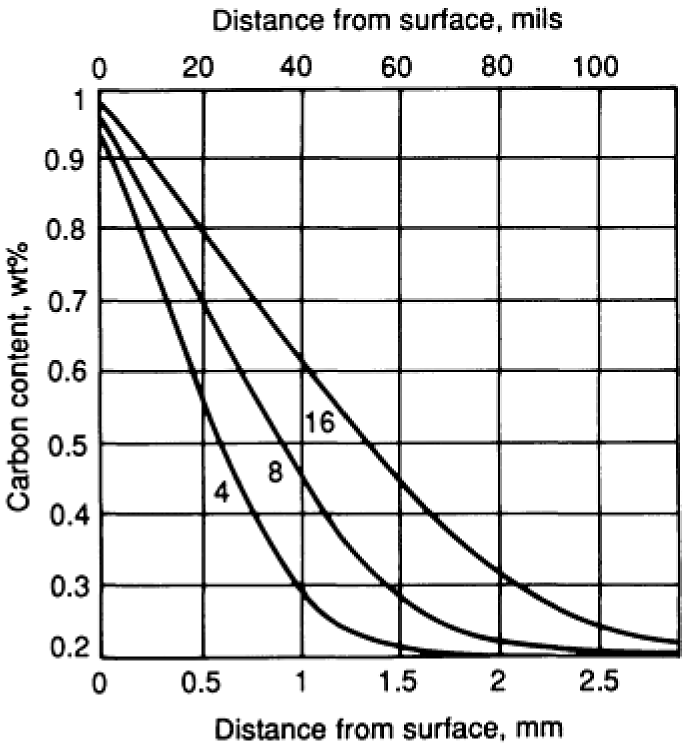

Fig. 1 Computed carbon concentration gradients resulting from gas carburization of SAE 8620 steel for 4, 8, and 16 h at 927 °C (1700 °F). Carbon potential of furnace atmosphere assumed to be 1 wt% C during process

Second, carburized cases are most frequently produced in thicknesses that range from 0.5 to 1.5 mm (20 to 60 mils). At 927 °C (1700 °F), which is a typical processing temperature, this thickness range can be produced in processing times from about 2 to 15 h. Cases as thin as 0.1 mm (4 mils), which require less than 10 min at 927 °C (1700 °F), are sometimes produced on small parts by salt bath carburizing. Cases as deep as 3 mm (120 mils), which require more than two days of carburizing at 927 °C (1700 °F), are occasionally produced on large parts. The ease of adjusting the case depth to resist the anticipated contact loading is one of the great advantages of carburizing.

The microstructure of martensitic steels varies with carbon content in two important ways. First, unalloyed steels with carbon contents of less than about 0.5/0.6 wt% form dislocated lath martensite upon quenching. Steels with carbon contents above 1.0% form twinned plate martensite. Mixtures of lath and plate martensite are found with intermediate carbon levels (Ref 3, 4). Thus, a carburized case will have a mixture of martensite morphologies, with plate martensite dominating in the high-carbon outer layers, and lath martensite dominating toward the core. Alloying elements, which strengthen austenite, promote the formation of plate martensite at lower carbon levels.

Over the same range in carbon as the transition from lath to plate martensite, the amount of austenite retained in the as-quenched structure increases (Fig. 2). However, the amount of austenite retained is a function of other variables, as well. It tends to increase as the quench rate decreases, and as the content of alloying elements increases. Thus, at a given carbon content, the austenite content of as-quenched parts can be higher than the values shown in Fig. 2.

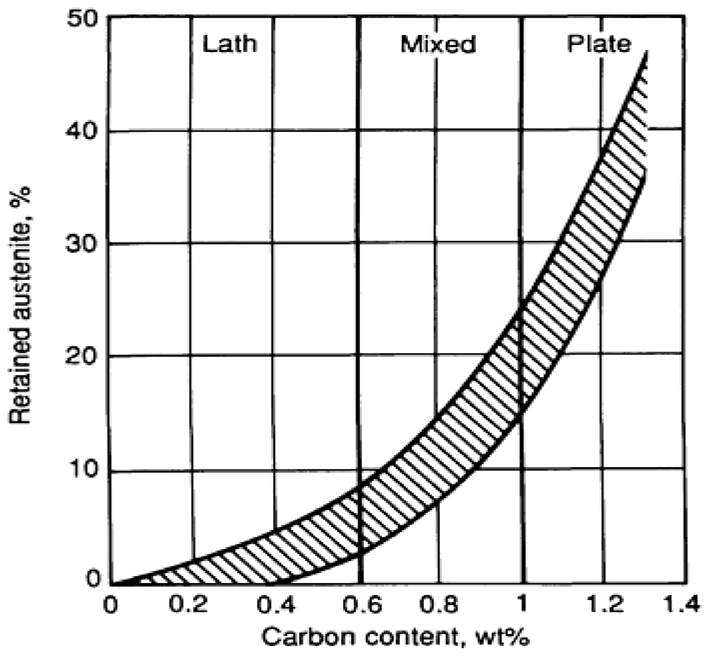

Fig. 2 Percent retained austenite as function of carbon content. Vertical lines show carbon ranges in which lath and plate martensites are found in Fe-C alloys. Source: Ref 5

For example, over 30% retained austenite can be produced in 52100 steel if all the carbon is dissolved during austenitization (Ref 6). In another example, a retained austenite content of 50% has been reported in SAE 8620 steel, with a case carburized to 0.9% carbon (Ref 7).

Although the hardness of martensite increases uniformly with carbon content, the hardness of the martensite-austenite composite obtained on quenching is usually reported to exhibit a plateau above approximately 0.6 wt% carbon (Fig. 3) (Ref 8, 9). In fact, most alloys, when carburized, oil quenched, and tempered at temperatures from 150 to 200 °C (300 to 390 °F), exhibit a maximum in hardness for case carbon contents in the range from 0.6 to 0.9% (Ref 10).

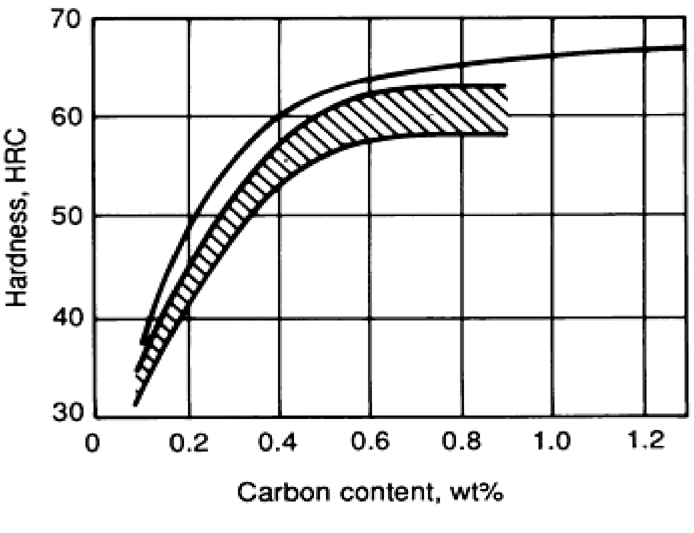

Fig. 3 Rockwell "C" hardness as function of carbon content. Upper curve, after Bain and Paxton (Ref 7), is their estimate of hardness of martensite, with shaded region above 0.9% C representing the uncertainty that is due to retained austenite. Lower band, after Crafts and Lamont (Ref 8), is their estimate of "the maximum hardness usually attained in commercial quenching."

The range in case hardness that is possible at a given carbon level for a variety of carbon steels is much broader than suggested by Fig. 3. (A highly alloyed carburizing steel, such as SAE 9310, may have a case hardness of less than 55 HRC after oil quenching.) When resistance to indentation is the primary concern, the case carbon content is usually specified to achieve the maximum in hardness.

Martensitic structures subjected to alternating shear stresses from repeated contact loading for extended periods of time are found to decompose because of carbon migration aided by dislocation motion (Ref 11). However, microstructural decay does not appear to be a necessary precursor to failure by the usual contact fatigue mechanisms.

Composite structures that contain primary carbides can also be produced by carburizing. Three common morphologies are discussed below.

Coarse primary carbides (from 1 to 10 μm, or 40 to 400 μin.) (Fig. 4) are produced by carburizing in an atmosphere with a carbon potential that is high enough to exceed the solubility limit for carbon in austenite. Coarse carbides are often found at corners and edges of parts made of alloys that are rich in strong carbide formers, such as chromium. Plate martensite and high levels of retained austenite can be found with coarse carbides in parts quenched directly from the carburizing temperature. Processing is sometimes designed to produce large primary carbides as a means of enhancing wear resistance (Ref 12). More often, large carbides are avoided, because they deplete the matrix in alloying elements such as Cr, thereby reducing hardenability.

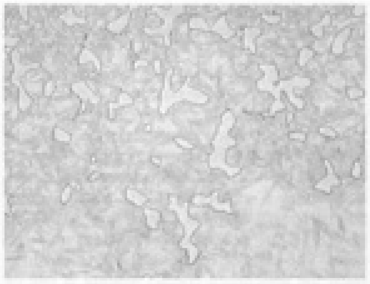

Fig. 4 Coarse primary carbides produced by carburizing SAE 4130 steel at 950 °C (1740 °F), and then quenching. Matrix microstructure is plate martensite and retained austenite. Picral etch. 600×

Carbide networks (Fig. 5) form in austenite grain boundaries when parts are carburized at an elevated temperature, and then slowly cooled. The solubility limit in austenite is exceeded as cooling occurs, and carbon is rejected to austenite grain boundaries. Because this structure tends to embrittle the case, it is usually avoided.

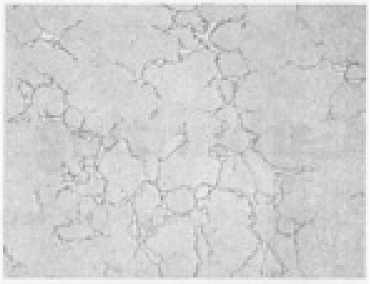

Fig. 5 Carbide networks in prior austenite grain boundaries. Produced by carburizing 4130 steel at 950 °C (1740 °F), furnace cooling to 800 °C (1470 °F), and then quenching. Picral etch. 600×

Fine primary carbides (from 0.1 to 0.5 μm, or 4 to 20 μin. diam) (Fig. 6) result when a part is carburized at a high temperature, such as 950 °C (1740 °F), cooled to form pearlite or bainite, and then reheated to a lower temperature, such as 830 °C (1525 °F), for a brief time and quenched. Because the carbon solubility at 950 °C (1740 °F) is on the order of

1.5 times the solubility at 830 °C (1525 °F), substantial quantities of fine carbides can be produced. The carbides will not coarsen significantly if the time at the lower austenitizing temperature is on the order of 30 min or less. Because the retained austenite content is a function of the carbon dissolved in austenite, the hardness will be near the maximum for the alloy. Finely dispersed primary carbides can incrementally increase the hardness. Their main contribution is in restricting austenite grain growth, thereby assuring fine martensite plates and finely dispersed retained austenite. Many gears and bearings are heat treated in this manner.

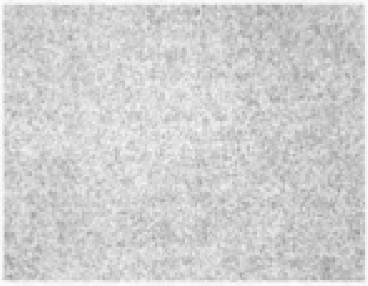

Fig. 6 Fine primary carbides in lath martensite produced by carburizing at 950 °C (1740 °F), air cooling to room temperature, then reheating to 820 °C (1510 °F) for 20 min and quenching. Picral etch. 600×

Residual Stress. Carburized parts usually contain compressive residual stresses in the high-carbon case. The stresses arise because of the sequence of transformations upon quenching (Ref 13). The higher the carbon content, the lower the temperature at which martensite begins to form. The lower the transformation temperature, the greater the volume increase upon transformation. Therefore, upon cooling, the core transforms first and the volume change is accommodated by plastic deformation of the austenitic case. When the case transforms, the martensitic core accommodates the volume increase in the case by elastic, rather than plastic, deformation. Consequently, compressive residual stresses in the case tend to be balanced by tensile residual stresses in the core.

Actual stress distributions can be more complex than the scenario above would suggest, because:

- Temperature gradients within the part cause transformation to begin below the case/core interface, and then progress inward and outward simultaneously
- Austenite that is retained upon quenching does not contribute to the case expansion

From a consideration of force balances, it follows that when the case is thin relative to the core, compressive residual stresses in the case will be high. If the case is thick relative to the core, compressive stresses in the case will be low and tensile residual stresses in the interior will be high. Compressive surface residual stresses are beneficial in applications involving torsional and bending loads, because the tensile stresses caused by these loads are a maximum at the surface. Compressive residual stresses are also beneficial in resisting rolling contact fatigue because they offset the tensile stresses responsible for initiating and propagating subsurface fatigue cracks (Ref 14, 15). However, in some parts, high compressive surface residual stresses can cause problems, such as case/core interface cracks at tooth tips in gears.

Residual stresses can be significantly reduced by tempering at temperatures up to 200 °C (390 °F), without greatly affecting either the hardness or retained austenite content (Ref 16). Changes in residual stress commonly occur during service (Ref 17).

Transformation of Retained Austenite. Under the action of elastic stresses or plastic deformation, retained austenite can transform to martensite (Ref 18, 19, 20). Transformation often occurs in service in parts that experience high contact loads. The surface hardness increases, and the resulting volume expansion increases the compressive residual stress at the surface. Carburized roller bearings typically contain from 30 to 40% retained austenite in the case. Lowering the retained austenite content usually has an adverse effect on rolling contact fatigue life (Ref 7, 21).

On the other hand, manufacturers of instrument bearings, who strive to maximize dimensional stability, make an effort to eliminate retained austenite (Ref 22). Similarly, in applications requiring the best resistance to indentation, the retained austenite content is kept low to maximize hardness. Ball bearings, for example, experience "point loading," whereas gears and roller bearings experience "line loading." Therefore, manufacturers of ball bearings, attaching more importance to indentation resistance, choose a through-hardened steel, SAE 52100, which is readily processed to yield from 5 to 10% retained austenite and hardness values greater than 62 HRC.

Surface Oxidation. Most carburizing is done in environments that contain some oxygen. An atmosphere capable of carburizing steel will also reduce iron oxides, but it often contains sufficient oxygen to oxidize alloying elements, such as Si, Mn, Cr, and V. During carburizing cycles of several hours duration, oxides of these elements will form at the surface and/or in grain boundaries intersecting the surface (Fig. 7).

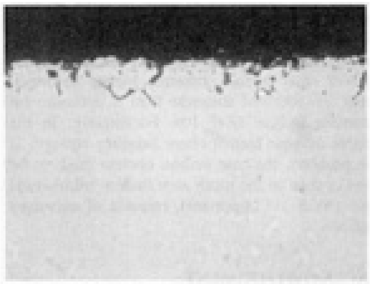

Fig. 7 Oxides formed at grain boundaries near the surface. Same sample as Fig. 5. Unetched. 600×

Depletion of these elements from the matrix can lower the hardenability enough to allow nonmartensitic products to form upon quenching, causing low hardness in a surface layer that is one to two grain diameters in thickness (Ref 23). Nonmartensitic products at the surfaces of gear teeth are known to reduce the tooth bending fatigue strength and would be expected to have an adverse effect on tribological properties, as well. If the matrix microstructure is unaffected, the effect of oxides on tribological properties is probably similar to that produced by oxide inclusions in the steel. Manufacturers of fine-pitch gears often do not attempt finishing operations to remove grain boundary oxides after heat treatment, arguing that the risk of surface damage caused by overheating during grinding outweighs any possible gain.

The thin layer of iron oxide that forms on carburized parts tempered in air at temperatures from 150 to 200 °C (300 to 390 °F) is usually benign. Thicker oxide layers, formed at higher temperatures, are sometimes used on steels as "break-in" coatings.

Carburizing Steels

Three factors are usually considered when selecting carburizing steels: cleanliness, hardenability, and fabricability, each of which is discussed below.

Cleanliness. For the best resistance to rolling contact fatigue (spalling), the content of aluminate, silicate, and globular oxide inclusions (Types B, C, and D, respectively, in the Jernkontoret system, ASTM E 45) must be as low as possible. Manganese sulfide inclusions (Type A) are generally not regarded as detrimental to rolling contact fatigue life (Ref 24).

The inclusion standards specified in ASTM A 534, "Carburizing Steels for Anti-Friction Bearings," have been steadily tightened since the late 1960s, reflecting improvements in steelmaking. Some individual steel suppliers claim to be able to furnish premium-quality carburizing steels with oxygen contents below 15 ppm, titanium contents below 30 ppm, and inclusion ratings considerably better than ASTM A 534. Calcium treatment of bearing-quality steels to modify aluminates, thereby improving machinability, is usually avoided, because of the possibility of forming large inclusions.

When sliding is combined with rolling contact, near-surface inclusions (including oxides formed in grain boundaries during heat treatment) promote pitting (Ref 25). The role of inclusions in most forms of sliding wear is not as well defined as their role in rolling contact fatigue, probably because the conditions that are possible at a sliding interface are more diverse and more difficult to characterize, than at a rolling contact interface. Some insight into possible effects of

inclusions on sliding wear comes from the machining literature (Ref 26). It is known that some inclusions in a steel workpiece can promote tool wear during machining, whereas others can reduce wear.

Hardenability. The alloy content of carburizing steels is usually selected on the basis of hardenability. If the application involves high contact loads (roller bearings, for example), the uncarburized core must be martensitic to prevent the subcase from yielding. An alloy that allows the part to attain full hardness (through-harden) in whatever quenchant is employed will be selected. The selection of an alloy with sufficient core hardenability almost always assures sufficient case hardenability. When contact loads are well within the capability of the case to support them, it is often not necessary nor desirable for the core microstructure to be martensitic. Shape distortion during quenching, for example, is usually reduced if the core transforms at a relatively high temperature to a nonmartensitic structure. For such parts, the alloying need only be sufficient to ensure case hardenability.

Jominy hardenability bands for alloy carburizing steels are described in the article "Hardenability Curves," in *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of *ASM Handbook.* Narrower bands for restricted hardenability steels (Ref 27) have been devised in response to user demands for more precisely defined hardenability. Modern steelmaking practice provides much better control over hardenability, through composition control, than is reflected in the older standards.

The Jominy bands for carburizing steels provide a means of comparing the core hardenability of steels. To ensure adequate case hardenability, one needs a Jominy band for the same base composition, with the carbon content raised to about 0.4 wt%. (This presumes that one wishes all of the case with a carbon content of 0.4% or greater to be fully hardened.) For common alloys, such as 1524, 4023, 5120, 8620, and 8720, a "low-side estimate" of the case hardenability is given by the Jominy bands for 1541, 4042, 5140, 8640, and 8740, respectively. For other carburizing steels, case hardenability must be estimated from the composition or determined experimentally (Ref 28).

Fabricability. Manufacturing considerations also influence alloy selection. SAE 8620 steel readily transforms after hot rolling and annealing to a ferrite-pearlite microstructure (150-180 Brinell hardness) that has good machinability. If fabrication is by cold forming, rather than machining, then SAE 4118 might be selected, because it can be softened to a lower hardness with better ductility than 8620.

In manufacturing small automotive gears, steel rod is often annealed to facilitate blank-making by cold forming. Blanks are then normalized to a higher hardness to facilitate subsequent gear hobbing.

Unfortunately, with increasing hardenability comes increasing difficulty in softening. This is particularly true in alloys such as 4815 and 9310, in which the transformation to pearlite is very sluggish, requiring about one day at 600 °C (1110 °F) for completion. Because microstructures are usually less than optimum, machining of these alloys is more difficult.

Other Considerations. Several secondary hardening carburizing alloys have been developed for applications that require resistance to elevated temperatures, such as helicopter gearing and rock drill bits (Ref 29, 30, 31, 32). These alloys make use of the precipitation of copper and/or M_2C and MC carbides to provide resistance to softening for temperatures up to 550 °C (1020 °F). Because they contain substantial amounts of Mo and V, these alloys resemble low-carbon versions of tool steels. Some of the alloys are difficult to carburize because of high Si and Cr contents; preoxidation prior to carburizing is necessary to permit carbon penetration (Ref 33). Secondary hardening alloys could also be useful in ambient-temperature applications in which lubrication is marginal, because the heat generated by intermittent metal-to-metal contact would not readily soften the underlying metal (Ref 34). The article "Microstructures and Properties of Carburized Steels" in *Heat Treating,* Volume 4 of *ASM Handbook* (1991) expands upon the discussion in this section.

Process/Materials Selection for Wear Resistance

The independent variables available for controlling the microstructure/properties of carburized cases are those that define the carburizing alloy (composition, cleanliness), and those that define the carburizing process (time/temperature/carbon-potential carburizing history, time/temperature quenching history, time/temperature tempering history). These tools provide a considerable degree of control over these microstructural features:

Martensite

- (a) Carbon content of source austenite
- (b) Plate size (austenite grain size)
- (c) Strength
- (d) Secondary hardening

Primary carbides

- (a) Size
- (b) Volume fraction

Retained austenite

- (a) Volume fraction
- (b) Carbon content

Nonmetallic inclusions and these global features:

- Case depth
- Residual stress distribution

which determine the tribological properties of the case. The combination of properties that is best for each application must then be decided.

The necessary case depth and case hardness can be estimated from a Hertzian stress calculation, but other microstructural objectives can be specified only qualitatively. For many applications, the following "rules of thumb" apply:

- Sufficient case depth and case hardness must be provided to prevent indentation or case crushing under the anticipated contact loads. For gears and bearings loaded in "line contact," a minimum case hardness of 58 HRC frequently is specified. When high contact loads are accompanied by sliding, the near-surface hardness (to a depth of about 50 μm, or 2 mils) may have to be raised to prevent shearing of surface layers.
- The retained austenite content should be as high as possible, consistent with the requirements of the rule above. The retained austenite content should be controlled by adjusting the case carbon content, not by subzero quenching after carburizing or by tempering at temperatures above 200 °C (390 °F)
- The tempering temperature chosen should be as low as possible, but above the surface temperatures anticipated in finishing operations and in service
- The content of nonmetallic inclusions should be no higher than that needed for economical machining
- Coarse primary carbides can be helpful in resisting abrasive wear. Fine primary carbides can permit more retained austenite at the same hardness level. Experiments should be conducted to verify any benefits presumed to be associated with primary carbides

For certain types of gearing, the selection of materials and processes is dominated by concerns with resistance to tooth bending fatigue, rather than the tribological properties of the surfaces in contact. The best resistance to high-cycle bending fatigue appears to be associated with lower case carbon contents, higher hardness, and less retained austenite than is optimum for contact fatigue (Ref 10). Fortunately, in the roots of gear teeth (where bending strength is important), the case carbon content tends to be lower than in the tooth area (where tribological properties are important), because of curvature effects.

Nitriding and Nitrocarburizing

F.T. Hoffmann and P. Mayr, Institute of Material Science (Germany)

Introduction

THE NITRIDING AND NITROCARBURIZING PROCESSES are, aside from carburizing, the most important thermochemical processes in heat treating industrial parts for the production of case-hardened surface layers. Layer of high hardness, which provide high resistance to corrosion and wear in addition to high fatigue strength, are produced by the diffusion of atomic nitrogen into the surfaces. Other advantages include very low distortion, because of the low temperatures involved and the absence of phase transformations, and high tempering resistance associated with the high hardness property at service temperatures below the nitriding temperature.

The original nitriding process used gaseous ammonia as the nitrogen source. Within the past 60 years, numerous nitriding and nitrocarburizing processes have been developed, some of them for specialized applications. Today, parts can be nitrided by using powders, salt baths, gaseous mixtures, amd plasma-assisted processes as nitrogen sources. Detailed information on the many forms of nitriding and nitrocarburizing are given in *Heat Treating,* Volume 4 of the *ASM Handbook* (1991).

Characteristics of Nitrided Surfaces

The structure of a nitrided layer comprises:

- A compound layer on the surface, consisting primarily of nitrides and carbonitrides of types Fe_4N and Fe_{2-3} (N,C). In addition, special nitrides are formed in steel that contain nitride-forming elements, such as aluminum, chromium, molybdenum, vanadium, and titanium. If specified by the user, the compound layer can be suppressed by a special nitriding practice
- A diffusion layer below the compound layer, composed of nitrogen in interstitial solution in the ferritic matrix in combination with nitride dispersions

The composition and microstructure of the nitride layer can be greatly affected by process selection and specific process parameters. The composition of the compound layer can be affected by the nitriding atmosphere. Higher temperatures or a longer nitriding time produce increased growth of the compound layer. The structure of the diffusion layer (that is, type, size, and distribution of the nitrides) can be affected by:

- The nitriding temperature
- The cooling rate from nitriding temperature to room temperature
- Low-temperature annealing after cooling to room temperature
- The type of steel being nitrided

High nitriding temperatures promote the formation of large, coarse distributed nitrides; low temperatures, promote the formation of finely dispersed nitrides. Slow cooling rates from nitriding temperature to room temperature, annealing treatments, or heating by stressing the parts favors dissolution, growth, and change in the nitride structure. The nitriding depth can be increased either by increasing the process temperature or by increasing the nitriding time. Increasing the content of nitride-forming elements in the material increases the hardness of the surface layer ad decreases the nitriding depth. Both the hardness and the depth parameters depend on the extent of nonferrous nitride formation.

In addition, the atmosphere composition and nitriding temperature (that is, the nitriding potential and the carbon potential of the atmosphere) affect the phase composition and the distribution of nitrogen and carbon in the compound layer. Investigations (Ref 1) have shown that if the carbon potential of a nitriding atmosphere is low, every nitriding process starts with decarburization of the matrix. Increasing carbon potential (when nitrocarburizing) and increasing nitriding potential (when nitriding) decreases decarburizing. This effect is present even when Armco iron is used. This leads to zones below the compound layer with a lower carbon content than in the matrix. The diffusion coefficient of carbon in the iron matrix is lowe than the diffusion coefficient of carbon in the nitride layer, but the solubility of carbon in the nitride layer is higher than the solubility of carbon in the iron matrix. Thus, after the formation of the compound layer, carbon diffusing to the surface is enriched in the compound layer at the interface with the iron matrix. Figure 1 is a plot of the compound layer composition as a function of nitriding time. The carbon content in this enriched zone depends on the type of forming nitride (that is, the nitriding potential of the atmosphere) and on the carbon content of the steel itself.

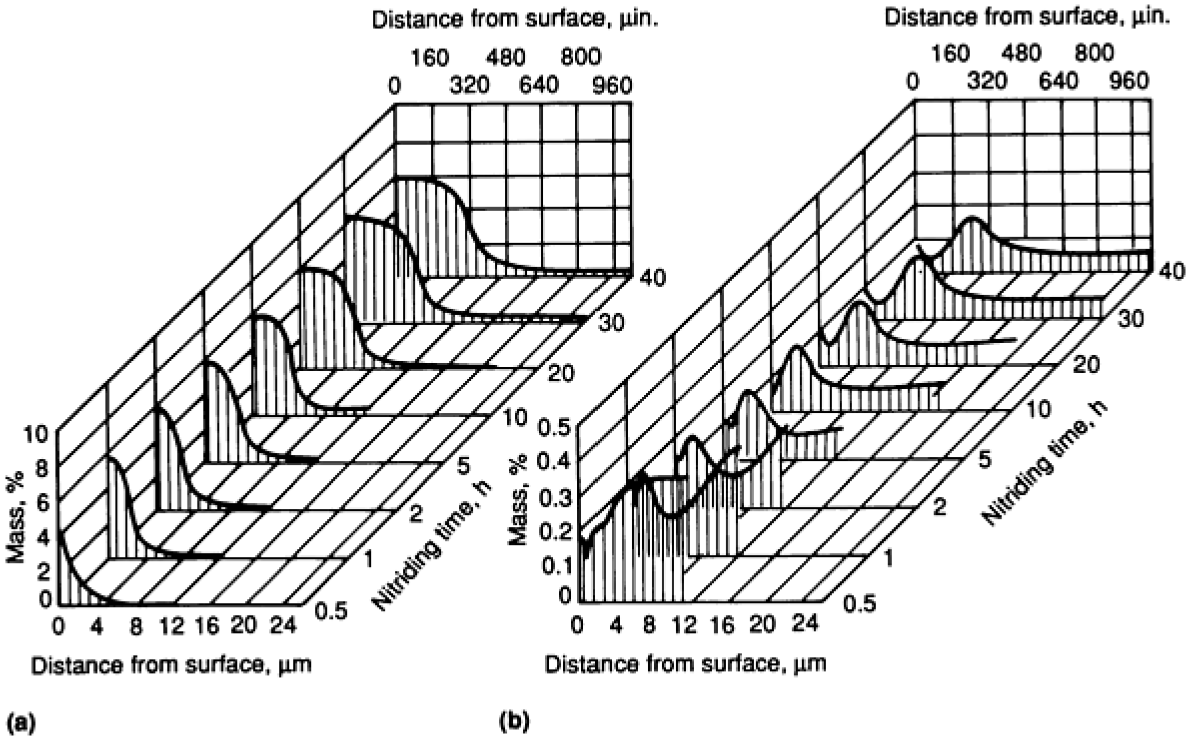

Fig. 1 Plot of compound layer concentration versus distance from the surface for Ck 45N nonresulfurized carbon steel as a function of gas nitriding duration. (a) Nitrogen distribution. (b) Carbon distribution. Nitrided at 540 °C (1005 °F). Nitriding number (K_N), 0.5

Wear Resistance of Nitrided and Nitrocarburized Materials

There are hundreds of articles in the literature that describe wear problems and their solution by different nitriding or nitrocarburizing processes. However, few of them describe the investigated nitride layers sufficiently. Most fail to specify the nitriding process, nitriding parameters, phase composition, compound layer thickness, and chemical composition and microstructure of the nitrided material. Therefore, the wear behavior of nitrided parts is somewhat difficult to ascertain from the literature. In this article, trends were deduced from recent, albeit contradictory, results (Ref 1, 2, 3, 4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21, 22, 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33) in order to make generalized statements on wear behavior.

The wear resistance of a nitride layer changes with distance from the surface (Fig. 2). Wear resistance is reduced in the porous zone of the compound layer because of the lower fatigue strength, reduced density, and the notch effect of the pores. The wear resistance of the poreless zone of the compound layer is significantly higher than that of the diffusion zone and the core material. If the compound layer has a homogeneous structure, wear resistance is constant throughout. In the diffusion layer, wear resistance decreases to the value of the core material with increasing distance from the surface;

this is because of the reduction of the density of the nitride precipitates and the supersaturation of the matrix with nitrogen.

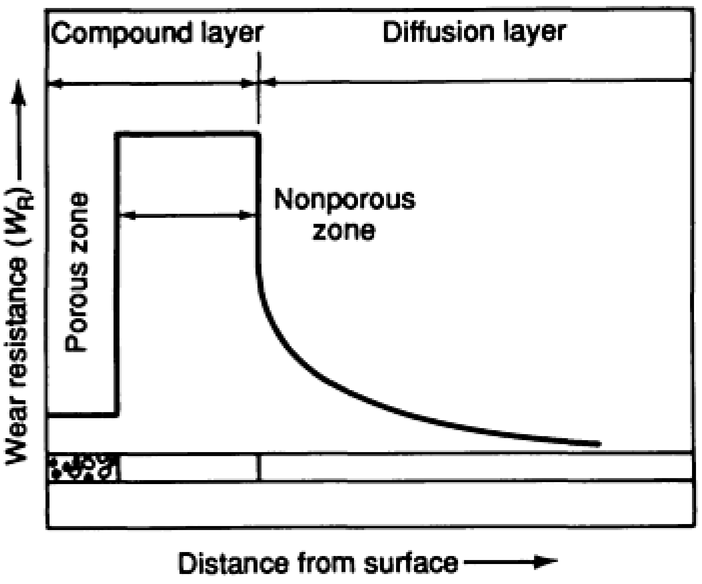

Fig. 2 Plot of adhesive and abrasive wear resistance versus distance from the surface for a nitride layer

The wear behavior of a nitride layer is often assumed to be an integral reaction of the nitriding layer to wear loading. This view does not explain wear mechanisms and their interaction during loading. Therefore, wear resistance and mechanisms must be discussed in conjunction with the structure of the nitriding layer. Table 1 gives the wear resistance of the compound layer and the diffusion layer in terms of the four major wear mechanisms discussed below.

Table 1 Effect of nitride layer on the wear resistance and the interaction parameter of metals as a function of wear mechanism

Wear mechanism	Interaction parameters		Relative wear resistance[b]	
	Compound layer[a]	**Diffusion layer[a]**	**Compound layer**	**Diffusion layer**
Adhesion	Structure	Formation of a protection layer (pl)	XXX	X
Tribo-oxidation	$v_{pl,form} > v_{pl,sol}$	$v_{pl,form} > v_{pl,sol}$	X	X
	$v_{pl,form} < v_{pl,sol}$	$v_{pl,form} < v_{pl,sol}$	[c]	[c]
Abrasion	Structure	Solid solution and precipitation hardening	XX	X

(a) $v_{pl,form}$, formation rate of friction-induced protective layer; $v_{pl,sol}$, solution rate of friction-induced protective layer.

(b) Increase relative to nonnitrided surface.

(c) Decrease in wear resistance

Adhesion. In adhesive wear, the wear resistance of the compound layer is very high compared with nonnitrided parts. This is because the inclination to microwelding decreases due to the change in the electron configuration in the outer region of the part. In the diffusion layer, wear resistance can also increase because of the formation of protective nitrogen-containing layers.

Tribo-oxidation. The wear resistance of the compound layer against tribo-oxidation depends on the formation of protective layers in the contact zone. If the formation rate, $v_{pl,form}$, of the friction-induced protective layer is greater than the concurrent solution rate, $v_{pl,sol}$, wear resistance increases. If $v_{pl,sol}$, > $v_{pl,form}$, wear resistance decreases. The wear resistance of the diffusion layer seems to be behave similarly.

Abrasion. The compound layer is very resistant to abrasive wear, because the structure of the compound layer allows only very low plastic deformation. Compared with nonnitrided steel, the wear resistance of the diffusion layer is higher--a result of the higher fatigue strength obtained by solid-solution strengthening and precipitation hardening.

Surface Fatigue. It is assumed that the wear resistance of nitrided parts to surface fatigue is higher than that of nonnitrided parts, as the changed lattice structure of the compound layer prevents plastic deformation. The diffusion zone has very high resistance to surface fatigue wear; here plastic deformations are very small because of solid-solution strengthening and precipitation hardening.

Influence of Variables on Wear Resistance of Nitrided Parts

Compound Layer. Variables that influence the wear resistance of the compound layer of nitrided parts are illustrated in Fig. 3, 4, 5, 6, 7, 8, and 9. A porous zone will raise the initial wear in the case of adhesive and abrasive wear (Fig. 3 and 4). If tribo-oxidation is the main wear mechanism, a large increase in wear resistance can occur (Fig. 5). This may be due to absorption of the lubrication medium and subsequent formation of a lubrication layer. In the case of surface fatigue (Fig. 6), compound layer thickness has no influence on wear resistance if the porous zone of the compound layer is small and the maximum of the true stress (σ_v) lies in the deeper regions of the compound layer or below it. If the thickness of the porous zone increases the distance from the surface of the maximum stress, wear resistance to surface fatigue will rapidly decrease.

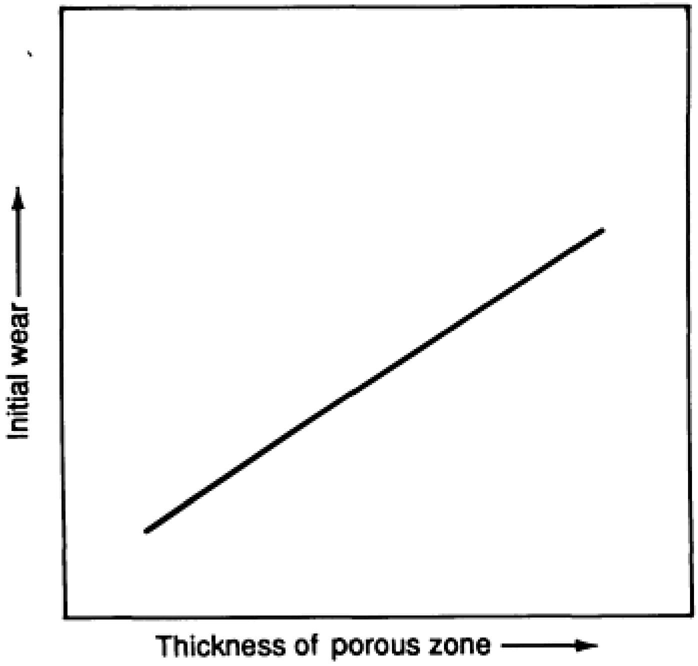

Fig. 3 Effect of porous zone thickness on adhesive wear resistance of the compound layer of a nitrided part

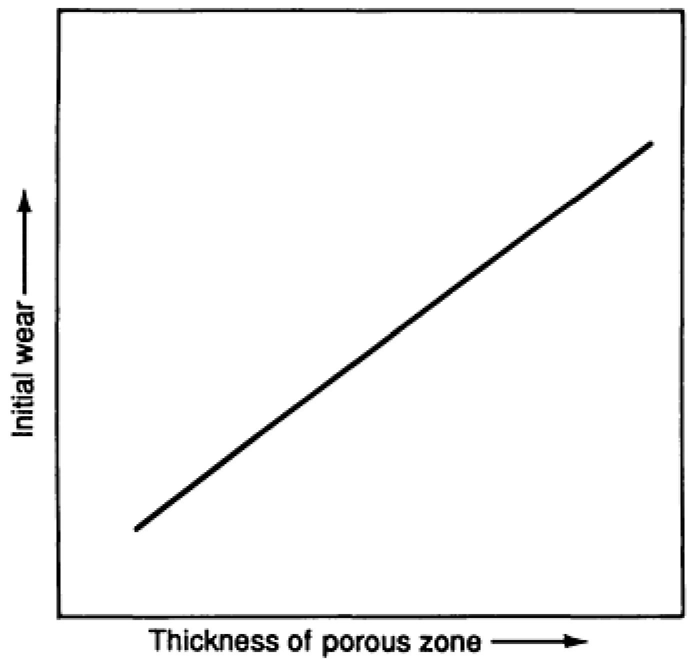

Fig. 4 Effect of porous zone thickness on abrasive wear resistance of the compound layer of a nitrided part

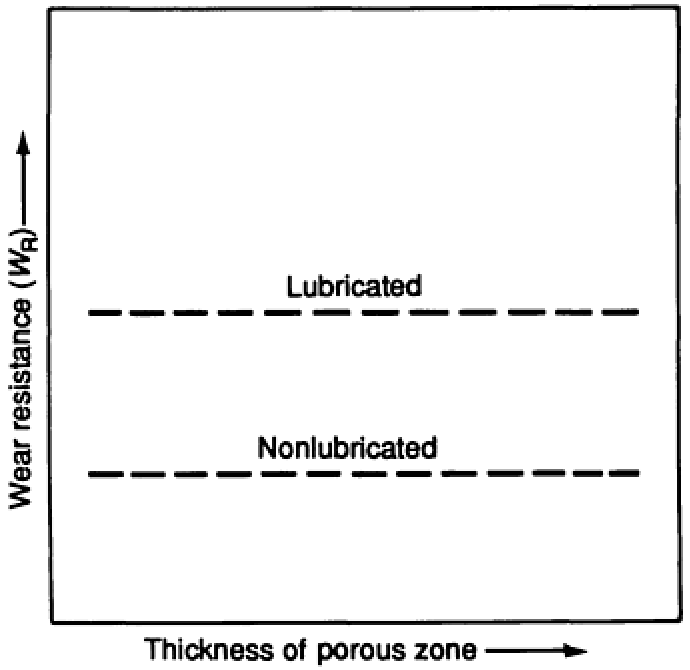

Fig. 5 Effect of lubrication on resistance of the compound layer of a nitrided part to wear caused by tribo-oxidation

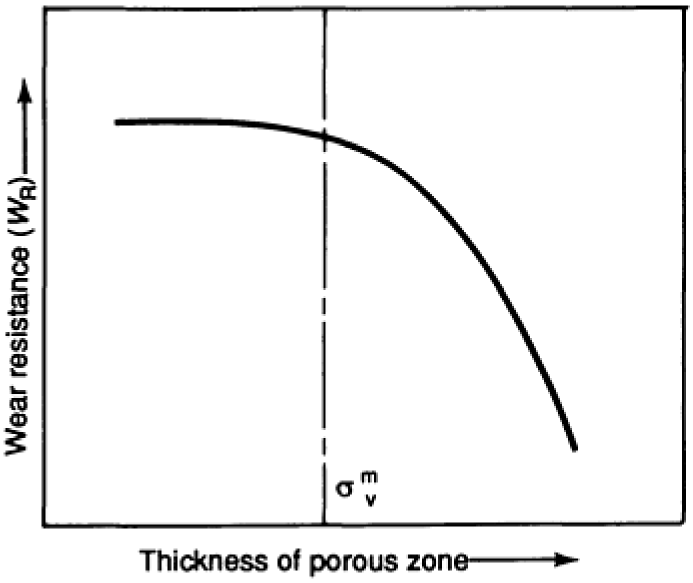

Fig. 6 Effect of porous zone thickness and maximum stress on resistance of the compound layer of a nitrided part to wear caused by surface fatigue

The structure and composition of the compound layer also influence its wear resistance. Investigations have shown that the adhesive wear resistance of the compound layer is strongly affected by the volume of ϵ-nitrides. In most cases, resistance increases with increasing ϵ-nitride content (Fig. 7). Similar behavior exists when nitrided parts are abrasively stressed (Fig. 8a). However, there is a difference between layers consisting only of nitrides and those containing carbonitrides. At constant volume of ϵ-nitride, carbonitride layers show significantly higher wear resistance than nitride layers (Fig. 8b). For surface fatigue, a higher content of ϵ-nitride in the compound layer will result increased wear resistance if the surface pressure is held constant (Fig. 9).

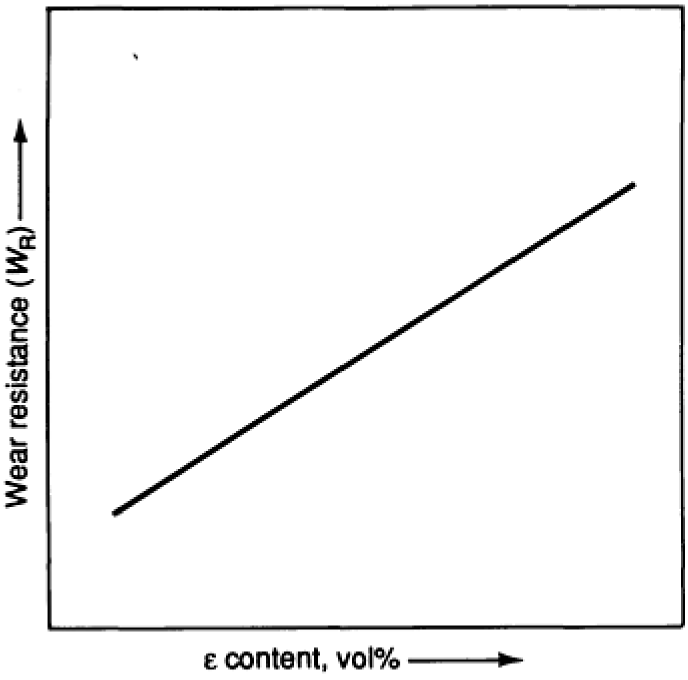

Fig. 7 Effect of ϵ-nitride content on adhesive wear resistance of the compound layer of a nitrided part

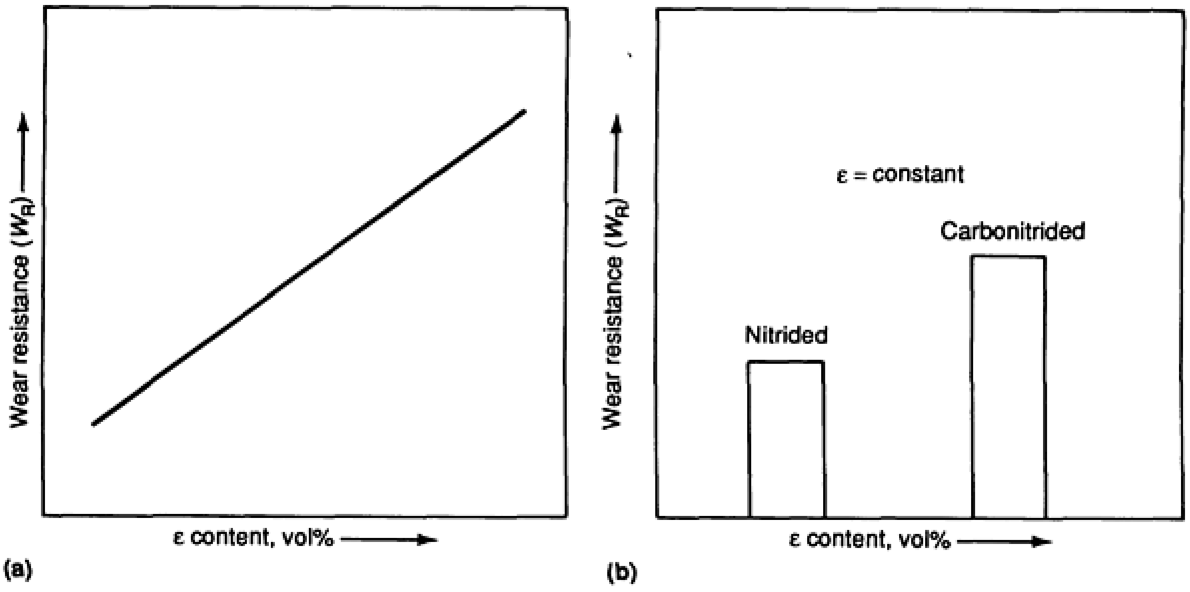

Fig. 8 Effect of ε-nitride content on abrasive wear resistance of the compound layer of a nitrided part. (a) Resistance increases with increasing εcontent. (b) At constant volume of ε, carbonitride layers show significantly higher resistance than nitride layers.

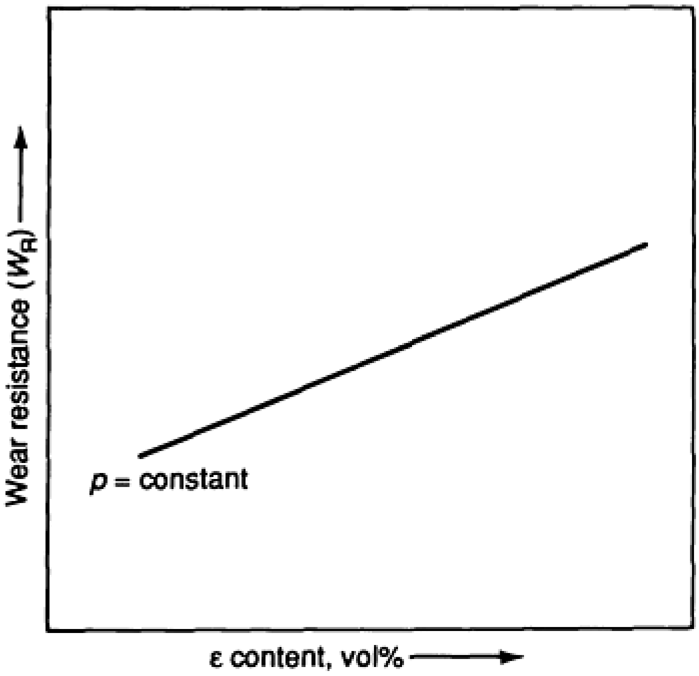

Fig. 9 Effect of ε-nitride content on resistance of the compound layer of a nitrided part to wear caused by surface fatigue at constant pressure

Diffusion Layer. Variables that affect the wear resistance of the diffusion layer of nitrided parts are illustrated in Fig. 10, 11, 12, 13, 14, 15, 16, and 17. Hardening of the alloy by precipitation methods such as solid-solution strengthening will raise the adhesive, abrasive, and surface fatigue wear resistance (Fig. 10 11 12). Greater nitriding depths also increase wear resistance (Fig. 13 14 15). Increases in the nitriding depth allow initial high wear resistance to abrasion to be upheld for a longer time, thus increasing component life (Fig. 14). Behavior is similar for surface fatigue stressing: increases in nitriding depth allow higher surface pressures and constant wear resistance (Fig. 15).

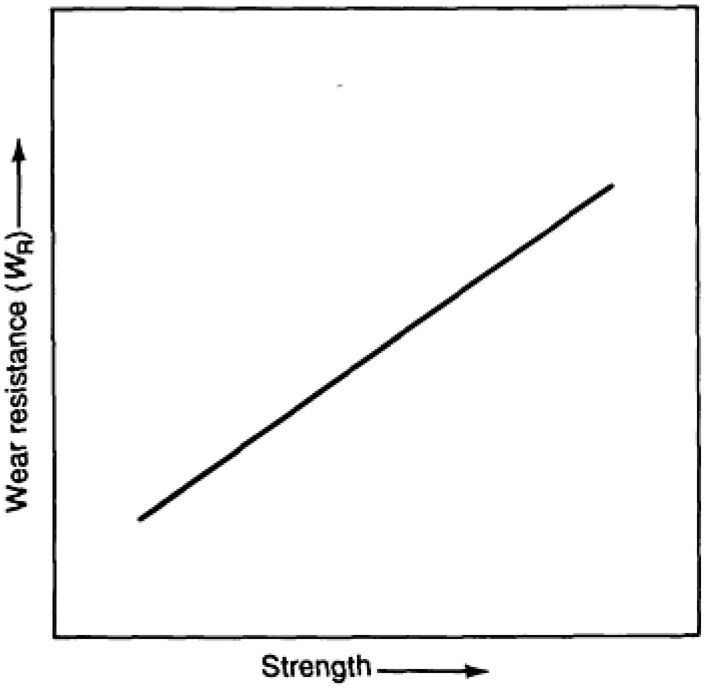

Fig. 10 Effect of material strength on adhesive wear resistance of the diffusion layer of a nitrided part

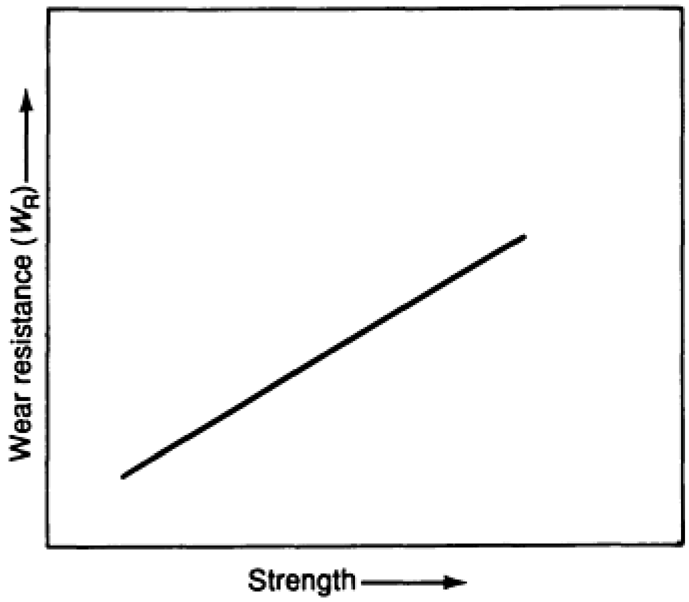

Fig. 11 Effect of material strength on abrasive wear resistance of the diffusion layer of a nitrided part

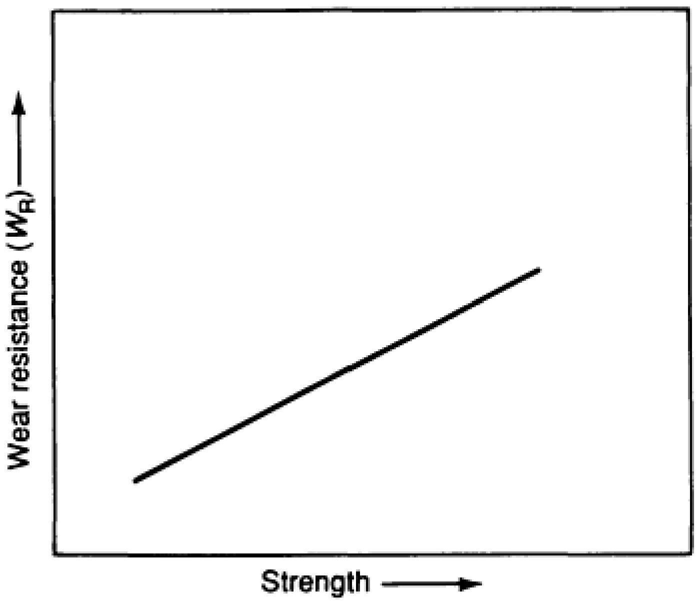

Fig. 12 Effect of material strength on resistance of the diffusion layer of a nitrided part to wear caused by surface fatigue

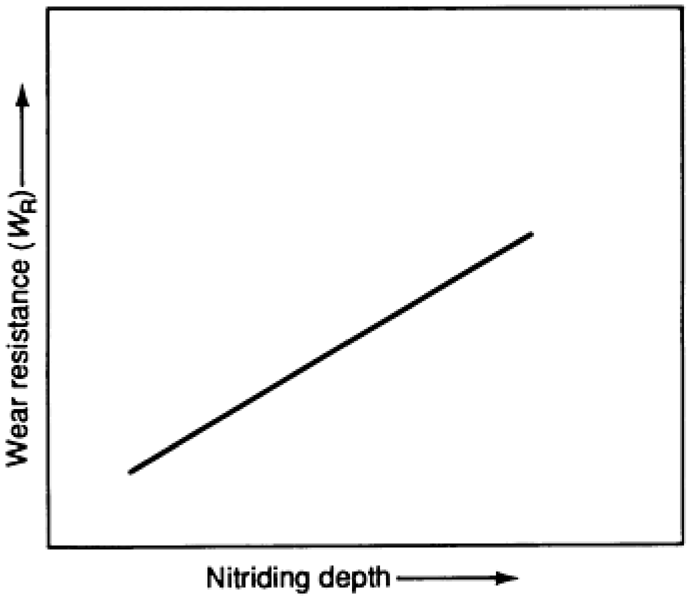

Fig. 13 Effect of nitriding depth on adhesive wear resistance of the diffusion layer of a nitrided part

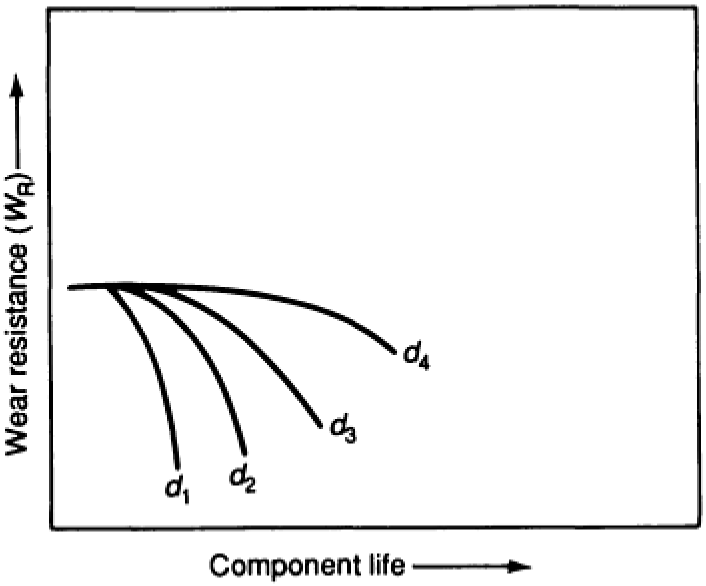

Fig. 14 Effect of nitriding depth on abrasive wear resistance of the diffusion layer of a nitrided part. Increases in nitriding depth increase component life. Nitriding depth, *d*: $d_1 < d_2 < d_3 < d_4$

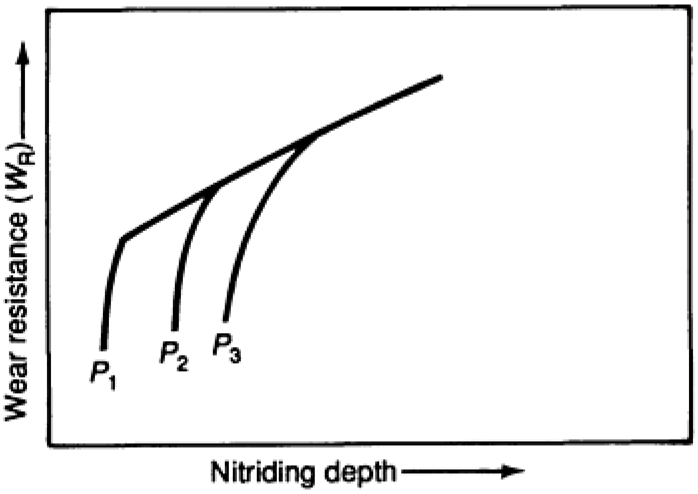

Fig. 15 Effect of nitriding depth on resistance of the diffusion layer of a nitrided part to wear caused by surface fatigue. Increases in nitriding depth allow the part to withstand higher surface pressures without sacrificing wear resistance. $p_1 < p_2 < p_3$

Nitride type and distribution in the diffusion layer can be changed by a postnitriding aging, strongly influencing wear resistance. For example, when nitrided parts are age hardened at constant temperature for different times, a characteristic hardness profile with a distinct maximum will result. Adhesive or abrasive wear stressing of such parts also results in a maximum wear resistance; however, the maximum shifts to higher aging times. Thus, both types of wear are sensitive to the type and distribution of the nitride precipitation in the diffusion layer: a matrix wit finely dispersed $Fe_{16}N_2$ nitrides has a lower wear resistance than one with a coarse distribution of Fe_4N nitrides (Fig. 16). The same is true for parts subjected to wear caused by surface fatigue (Fig. 17).

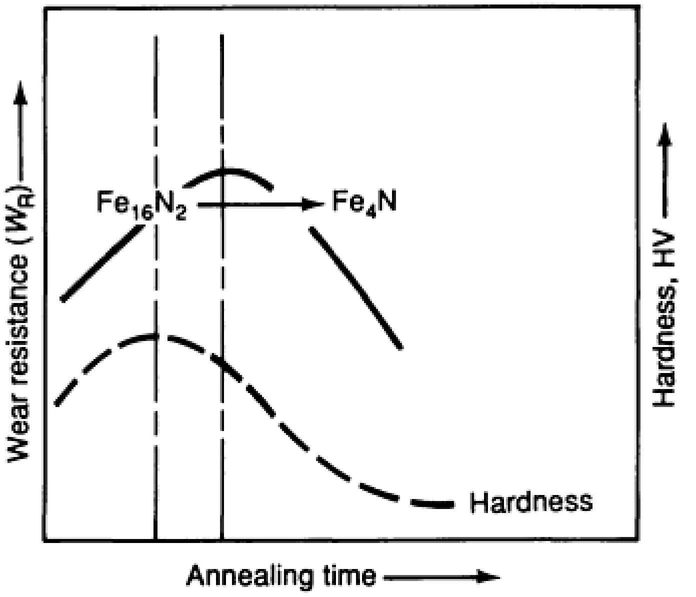

Fig. 16 Hardness profile showing effect of annealing time on abrasive and adhesive wear resistance of the diffusion layer of a nitrided part. See text for discussion of the effect of type and distribution of nitrides.

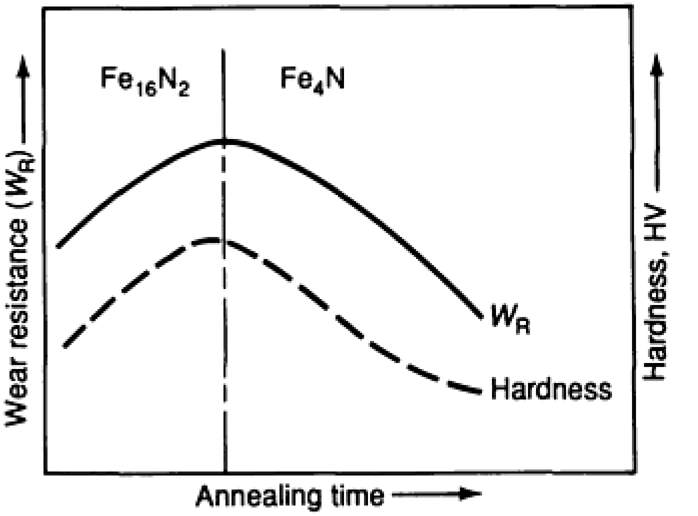

Fig. 17 Hardness profile showing effect of annealing time on resistance of the diffusion layer of a nitrided part to wear caused by surface fatigue. See text for discussion of the effect of type and distribution of nitrides.

Influence of the Nitriding/Nitrocarburizing Process on Wear Behavior

Investigations of the influence of the nitriding process on wear behavior can be divided into two groups: process oriented and materials science oriented. The objective of process-oriented investigations is often to show the clear advantages of a certain process. Materials-science-oriented investigations are usually more varied. Evaluation of published results of experimental work indicates that nitriding process variables do not exert much influence if nitriding layers are compared and are optimized to the actual wear stress.

Process variables do have an influence, however, if changes in geometry, which depend on the process, are considered. Typical process-dependent changes in geometry are shown in Table 2. Parts with elevations at their corners will have

shorter lifetimes because of the higher surface pressures at the corners than parts with constant surface pressures over the entire contact zone.

Table 2 Effect of nitriding process on surface topography and surface finish

Nitriding process	Material cross section showing surface topography	Nitriding parameters: Temperature °C (°F)	Nitriding parameters: Duration, h	Total roughness peak-to-valley (R_t), μm	Total roughness peak-to-valley (R_t), μin.	Arithmetic average surface roughness (R_a), μm	Arithmetic average surface roughness (R_a), μin.
Before nitriding		. . .	. . .	1	40	0.21	8.4
Plasma nitrided (bearing surface nitrided)		530 (985)	24	5	200	0.58	23
Plasma nitrided (totally nitrided)		550 (1020)	2	6	240	0.62	25
		550 (1020)	24	6	240	0.67	27
Salt-bath nitrided		570 (1060)	4	11	440	1.22	49
Gas nitrided		500 (930)	36	11	440	1.06	42
		500 (930)	84	13	520	1.21	48

Optimization of Wear by Process Technology

The influence of nitriding process parameters on wear resistance is not very high, but, with limitations, specific wear properties can be fitted to loading conditions by process optimizing. Table 3 summarizes possible enhancements of wear resistance for various wear mechanisms.

Table 3 General guidelines for improving the wear resistance of nitrided and carbonitrided steels as a function of wear mechanism and surface layer type

Layer	Wear mechanism(s)	Action required to improve wear resistance	Recommended change in process parameter
Compound layer	Abrasion, adhesion	Optimization of structure: • Transform γ' to ϵ microstructure by using higher nitriding potentials • Convert from nitriding to carbonitriding to add additional carbon donors • Minimize porous zone region by polishing surface	Modify nitriding atmosphere: • Salt bath: change content of base from CN^- to CNO^- • Gaseous: change nitriding number, flow rate, and carbon donors
		Formation of reactive layers	Add oxidation process after nitriding process is completed
	Tribo-oxidation	Modification of tribosystem	. . .
	Surface fatigue	Reduction in size of porous zone	Modify nitriding atmosphere
Diffusion layer	Abrasion, adhesion	Increase strength of material	Select alternate materials, add heat treatment prior to nitriding (use hardening and tempering operations instead

	Tribo-oxidation	Modification of tribosystem	. . .
	Surface fatigue	Optimization of hardness profile	Increase temperature and duration of nitriding process; select alternate materials; add heat treatment prior to nitriding; increase cooling rate after nitriding; add annealing treatment after nitriding
		Modification of composition (type, form, particle size, and distribution of nitrides) to	. . .

Adhesive or Abrasive Wear. In adhesive or abrasive wear, the properties of the compound layer must be optimized by:

- Changing γ'-nitride to ϵ-nitride by higher nitriding potentials (nitriding numbers)
- Changing nitrides to carbonitrides by adding carbon donors such as Endogas and CO_2 or by using a material with a higher carbon content
- Minimizing the porous zone by polishing

Porosity can also be influenced by the atmosphere (for example, lower nitriding potential or lower content of carbon donors), but this may worsen the properties of the compound layer. However, a small porous zone in the compound layer may be advantageous when the shape of the surface can be optimized by running-in (initial) wear.

In gas nitriding, the structure of the compound layer can be changed by a definite nitriding atmosphere--that is, a definite nitriding number [ratio $p(NH_3)/p(H_2)^{1.5}$] or by additional carbon-containing gases such as CO_2 or Endogas. In plasma nitriding, additional parameters such as pressure and glow discharge conditions are beneath the atmosphere. In bath nitriding, the concentration of the cyanate and cyanide content of the bath can be changed.

A reaction layer can be formed by an oxidation process after nitriding. Usually, these processes are performed in salt baths or in gaseous atmospheres.

The adhesive and abrasive wear resistance of the diffusion layer can be enhanced by strengthening the diffusion layer. The most effective means of this are by proper material selection (for example, high content of nitride-forming elements) and by heat treatment before nitriding (for example, hardening and tempering instead of normalizing).

Tribo-oxidation. If tribo-oxidation is the primary wear mechanism, only limited improvements can be made by changing the nitriding conditions. In this case, it is necessary, if possible, to change the conditions of the tribosystem.

Surface Fatigue. If controlling surface fatigue is the objective, measures to optimize the diffusion layer can be effective--in particular, fitting the nitriding hardness profile to the stressing profile and influencing the nitride precipitates (type, form, size, and distribution). The choice of material and heat treatment before nitriding depend on the required core strength. Nitriding of alloyed steels often results in thick deposits of carbides and/or nitrides in the grain boundaries, which may promote crack initiation. If the parts are to be under high load, such deposits should be avoided by changing the heat treatment process.

The nitriding depth can be increased by increasing process temperature and/or treating time. If merely prolonging the nitriding time does not result in sufficient nitriding depths, a two-step process can be performed. In the first step, nitriding is done at low temperatures to generate a finely dispersed nitride distribution. The second nitriding step is done at higher temperatures to raise the nitriding depth. This procedure avoids coarsening of the nitride distribution and thus a decrease in hardness. The cooling rate from the nitriding temperature and postnitriding treatments can be used to influence the type, size, and distribution of the nitrides.

Corrosive Wear. Nitriding improves resistance to corrosive wear. Resistance can be further improved by oxidation of the compound layer after nitriding. To achieve a very smooth layer capable of sustaining high loads, it is recommended that the oxidized layer be polished and then oxidized again.

Glossary of Terms

Compiled by Peter J. Blau, Metals and Ceramics Division, Oak Ridge National Laboratory

WORDS AND PHRASES are the essential tools of technical communication. Without clearly defined terminology, technological progress is impossible. The written and spoken word must be precise and mutually understood by all communicating individuals in the same context. Unfortunately, the terminology used in friction, lubrication, and wear science and technology ("tribology") has evolved from sources in many different scientific and engineering fields. Some terms (especially hyphenated terms) are coined during wear failure analysis and do not necessarily conform to existing terminology. Consequently, the terminology varies greatly in origin and breadth of accepted usage. Terms also vary in specificity; that is, many terms with slightly different connotations are sometimes erroneously substituted for one another. For example, in certain instances the surface of a plain bearing might be described alternately as being polished, burnished, or scuffed. Strictly speaking, these three terms are not equivalent. The use of tribology terminology also varies between different English-speaking countries. A term such as *density* can be rather clearly and unambiguously defined, but scuffing cannot because too many different interpretations of the term are in common use. To avoid confusion and misunderstanding, terms which are known to have several possible interpretations should not be used.

Any compilation of a glossary of terms in tribology becomes a difficult task because, to be truly successful, it should remove ambiguity and form a basis for future usage. However, the glossary must also allow users to find definitions for terms that are deeply entrenched in the literature of the field even though they might be vague or inconsistently used. Avoiding the pit-falls of providing too narrow a series of definitions and descriptions of terms necessitated using a variety of references in assembling this glossary. The definitions obtained from these references are supplemented by additional ones written specifically for this Volume in order to provide more complete coverage. Sometimes the definitions presented in the cited references were inconsistent with the style or intent of this glossary and were edited. When such editing was necessary, the reference number is followed by the letter "m." More than one entry was provided for certain terms in order to show differences in common usage. In addition to the definitions given here, the reader is referred to articles dealing with specific fields where additional terminology is provided (for example, the parts of a bearing or the types of lubrication).

The basic form of an entry in the glossary contains the word or phrase in boldface type, one or more definitions and/or notes, a reference number (no reference number is given if the definition was written for this glossary), and additional information about synonyms and/or related terms as follows:

- **term in boldface type.**
  - (1) First definition. *Note:* a note contains supplementary clarifying material not required in the formal definition (Ref *X*). (2) Another definition, possibly from another source (Ref *Y*). Synonym or see also *another term*

Not all terms in the cited references were included here for various reasons. For example, a given term might occasionally be used in tribology, but is not principally associated with friction, lubrication, and wear (for example, *belleville spring*), or the definition from one source was nearly identical to that from another and need to be repeated.

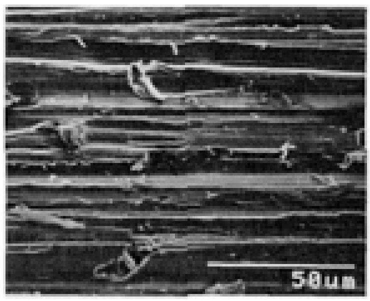
While the editors have attempted to coordinate the use of terminology throughout this Volume, we can offer no guarantee that the terminology used in the other Sections of this Handbook is entirely consistent with the definitions presented in this glossary. As with friction, lubrication, and wear technology as a whole, this Volume was compiled by individuals with backgrounds in many different fields.

To further clarify certain terms in this glossary, illustrations or photographs are included. Photographs, like written language, leave some room for precision, and examples were chosen to represent the general case of the phenomenon, not necessarily the only way in which a certain tribological phenomenon can appear.

- **A**
- **a-spot**
  - One of many small contact areas through which electrical current can pass when two rough, conductive, solid surfaces are touching. *Note:* This term derives from the analysis of R. Holm in

modeling electrical contact behavior. A-spots may represent an area smaller than the total asperity contact area referred to in other surface contact models.

- **Abbott-Firestone curve**
  - Introduced in 1933 by E.J. Abbott and F.A. Firestone and sometimes called a "bearing area curve," the Abbott-Firestone curve is a plot of depth below a reference level parallel to a solid surface (ordinate) versus the percent bearing area intercepted by a horizontal line at that depth (abscissa). *Note:* The Abbott-Firestone curve is sometimes used to compare the load-supporting behavior of bearings with different surface roughnesses. See also bearing area .
- **abrasion**
  - A process in which hard particles or protuberances are forced against and moving along a solid surface. *Note:* Sometimes this term is used to refer to abrasive wear . See also abrasive erosion .
- **abrasive erosion**
  - Erosive wear caused by the relative motion of solid particles which are entrained in a fluid, moving nearly parallel to a solid surface (Ref 1m). See also erosion
- **abrasive wear**
  - Wear by displacement of material caused by hard particles or hard protuberances (Ref 1). Wear due to hard particles or hard protuberances forced against and moving along a solid surface (Ref 2).



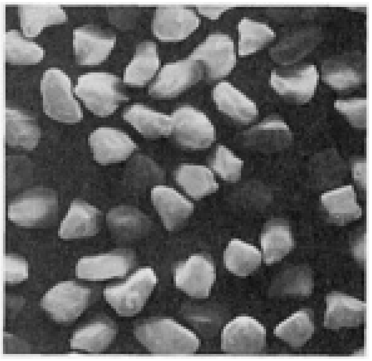
Abrasive wear of the surface of 1020 steel abraded by 220 grit SiC paper showing characteristic grooves and attached, tiny cutting chips. Courtesy of L.K. Ives, NIST

- **abrasive wear factor**
  - An empirical factor (f_v) that expresses the influence of various service environments on the increase in the radial clearance of a bearing (*V*) and, hence, the extent of life reduction as:

$$f_v = (V/e_0)$$

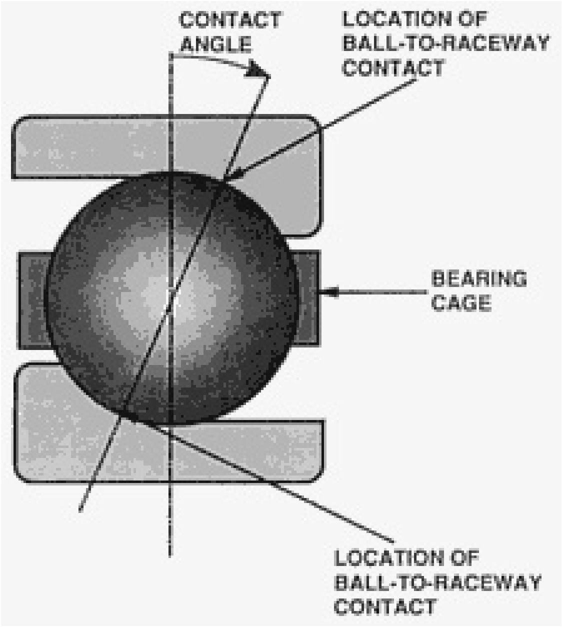
  - where e_0 is a geometrical factor (Ref 3, p 699).
- **abrasivity**
  - The extent to which a surface, particle, or collection of particles will tend to cause abrasive wear when forced against a solid surface under relative motion and under prescribed conditions. *Note:* Specifically, an ASTM standard for the abrasivity of slurries--ASTM G 75--has been developed.
- **absolute impact velocity**
  - See impact velocity .
- **asolute viscosity**
  - See viscosity .
- **acceleration period**
  - In cavitation and liquid impingement erosion, the stage following the incubation period, during which the erosion rate increases from near zero to a maximum value (Ref 2).
- **accessory seal**
  - On various types of engines, a seal that is employed for sealing an accessory shaft in the gear box, such as a shaft for operating an oil pump, a fuel pump, a generator, a starter, or a de-oiler (Ref 4m).
- **accumulation period**

- See preferred term acceleration period .
- **actual contact area**
  - The total area of contact formed by summing the localized asperity contact areas within the apparent area of contact . Also known as real area of contact .
- **actual slip**
  - See macroslip .
- **additive**
  - In lubrication, a material added to a lubricant for the purpose of imparting new properties or of enhancing existing properties. *Note:* Main classes of additives include anti-corrosive , antifoam , antioxidant , antiwear , detergent , dispersant , extreme-pressure , and VI improver additives (Ref 1m).
- **adherence**
  - In tribology, the physical attachment of material to a surface (either by adhesion or by other means of attachment) that results from the contact of two solid surfaces undergoing relative motion. *Note:* Adhesive bonding is not a requirement for adherence because mechanisms such as mechanical interlocking of asperities can also provide a means for adherence. See also adhesion (adhesive force) and adhesion, mechanical .
- **adhesion (adhesive force)**
  - In frictional contacts, the attractive force between adjacent surfaces. *Notes:* In physical chemistry, adhesion denotes the attraction between a solid surface and a second (liquid or solid) phase. This definition is based on the assumption of a reversible equilibrium. In mechanical technology, adhesion is generally irreversible. In railway engineering, adhesion often means friction (Ref 1).
- **adhesion, mechanical**
  - Adhesion between surfaces produced solely by the interlocking of protuberances on those surfaces. See also adherence .
- **adhesion coefficient**
  - See coefficient of adhesion .
- **adhesive wear**
  - (1) Wear by transference of material from one surface to another during relative motion due to a process of solid-phase welding. *Note:* Particles that are removed from one surface are either permanently or temporarily attached to the other surface (Ref 1). (2) Wear due to localized bonding between contacting solid surfaces leading to material transfer between the two surfaces or loss from either surface (Ref 2).
- **aerodynamic lubrication**
  - See gas lubrication .
- **aerostatic lubrication**
  - See pressurized gas lubrication .
- **AFBMA**
  - Abbreviation for Anti-friction Bearing Manufacturers' Association, an organization that produces specifications, such as the grading system for the quality of bearing geometry and finish, for the bearing industry.
- **AFS 50-70 test sand**
  - A rounded quartz sand specified for use as an abrasive in the dry sand-rubber wheel abrasive wear test (ASTM G 65). *Note:* Using the U.S. Sieve Series, none of this sand will be retained on Sieve No. 40, 5% maximum will be retained on Sieve No. 50, 95% minimum will be retained on Sieve No. 70, and none will pass Sieve No. 100. This places all the particle diameters between 425 and 150 μm.



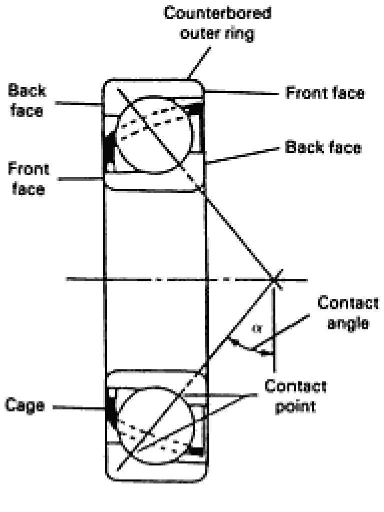
AFS 50-70 test sand particles used in the ASTM dry sand-rubber wheel abrasion test. Courtesy of L.K. Ives, NIST

- **age hardening (of grease)**
  - The increasing consistency of a lubricating grease with time of storage (Ref 1).
- **air bearing**
  - A bearing using air as a lubricant (Ref 1). See also gas lubrication and pressurized gas lubrication .
- **air hammer**
  - In lubrication, a type of instability, basically a resonance, that occurs in externally pressurized gas bearings (Ref 1).
- **aligning bearing**
  - A bearing with an external spherical seat surface that provides a compensation for shaft or housing deflection or misalignment (Ref 1). Compare with self-aligning bearing .
- **Alpha Model 1**
  - A type of wear-testing machine consisting of a conforming or flat-faced block pressed vertically downward by a deadweight loading arrangement against the circumference of a hardened steel ring that is rotating on a shaft. *Note:* This term is based on manufacturer's designation, but has become common terminology for referring to the block-on-ring geometry. Further information can be found in ASTM Standard Test Method G 77.
- **Amontons' laws**
  - Two laws propounded in 1699 that state that (1) friction force is proportional to normal force, and (2) friction force is independent of the size of the contact area (Ref 1).
- **Amsler wear machine**
  - A wear and traction-testing machine consisting of two disk-shaped specimens oriented such that their axes are parallel and whose circumferential, cylindrical surfaces are caused to roll or roll and slide against one another. *Note:* The rotation rates of each disk may be varied so as to produce varying degrees of sliding and rolling motion.
- **angle of attack**
  - The angle between the direction of motion of an impinging liquid or solid particle and the tangent to the surface at the point of impact (Ref 2).
- **angle of contact**
  - In a ball race, the angle between a diametral plane perpendicular to a ball-bearing axis and a line drawn between points of tangency of the balls to the inner and outer rings (Ref 1).



Angle of contact in an angular-contact bearing

- **angle of incidence**
  - The angle between the direction of motion of an impinging liquid or solid particle and the normal to the surface at the point of impact (Ref 2).
- **angular-contact bearing**
  - A ball bearing of the grooved type, designed in such a way that when under no load, a line through the outer and inner raceway contacts with the balls to form an angle with a plane perpendicular to the bearing axis (Ref 1).



Angular-contact bearing.

- **annular bearing**
  - (1) Usually a rolling bearing of short cylindrical form supporting a shaft carrying a radial load (Ref 1). (2) A flat disk-shaped bearing (Ref 1).
- **aniline point**
  - As applied to a petroleum product, the lowest temperature at which the product is completely miscible with an equal volume of freshly distilled aniline. *Note:* The aniline point is a guide to the oil composition (Ref 1).

- **anticorrosive additive**
  - A lubricant additive used to reduce corrosion (Ref 1m).
- **antiextrusion ring**
  - A ring that is installed on the low-pressure side of a seal or packing, in order to prevent extrusion of the sealing material (Ref 4).
- **antifoam additive**
  - An additive used to reduce or prevent foaming (Ref 1m). Also known as foam inhibitor .
- **antifriction bearing**
  - A bearing containing a solid lubricant (Ref 1m). *Note:* Historically, the term antifriction arose from the relatively slow starting torque of roller bearings compared with sliding bearings. See also roller bearing , rolling-element bearings, and self-lubricating bearing .
- **antifriction material**
  - A material that exhibits low-friction or self-lubricating properties.
- **antioxidant**
  - Any additive for the purpose of reducing the rate of oxidation and subsequent deterioration of oils or greases (Ref 5).
- **antiscuffing lubricant**
  - A lubricant that is formulated to avoid scuffing. *Note:* Antiscuffing lubricant has been suggested as a more accurate alternative to the term extreme-pressure lubricant .
- **antiseizure property**
  - The ability of a bearing material to resist seizure during momentary lubrication failure (Ref 1).
- **antiwear additive**
  - A lubricant additive used to reduce wear (Ref 1m).
- **antiwear number**
  - (AWN). A variant of the wear coefficient (*k*) suggested by Archard and defined as follows:

$$\text{AWN} = -\log_{10} k$$

  - See also Archard wear law .
- **antiweld characteristic**
  - See antiseizure property .
- **API gravity (API degree)**
  - A measure of density used in the U.S. petroleum industry where (Ref 1):

$$\text{Degrees API} = [141.5/\text{specific gravity at } 60\ ^\circ\text{F}) - 131.5$$

- **Apiezon oil**
  - An oil of low vapor pressure used in vacuum technology (Ref 1m).
- **apparent area of contact**
  - In tribology, the area of contact between two solid surfaces defined by the boundaries of their macroscopic interface (Ref 2). Contrast with real area of contact . See also Hertzian contact area and nominal contact area .
- **Archard wear law**
  - Introduced in 1953 by J.F. Archard, the Archard wear law expresses a proportionality among the sliding wear volume (*V*), the normal load (*W*), the total sliding distance (*S*), and the hardness (*H*) of the wearing surface:

$$V = \frac{kWS}{3H}$$

  - where *k*, the constant of proportionality, is often referred to as the "Archard wear constant," the "Archard wear coefficient," or simply the "wear coefficient" or the "wear constant." The use of the word "constant" in this context is not recommended. In some instances, the denominator is replaced with the flow pressure (*P*). *Note:* The simplicity of this linear law does not inherently

address the effects of sliding velocity, environment, or nonlinear sliding behavior associated with running-in and other wear transitions. See also wear coefficient , wear constant , and wear factor .

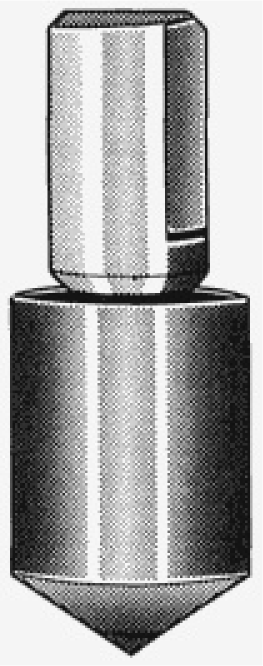
- **area of contact**
  - A general term that, without other modifying terminology, is insufficiently specific to be defined precisely. Its use should therefore be avoided. Related terms are actual area of contact, apparent area of contact , Hertzian contact area , nominal area of contact , and real area of contact .
- **asperities**
  - (1) The small-scale irregularities on a surface (Ref 1). (2) Minute imperfections on a seal face or surface of a mating ring that are the result of normal surface finishing processes (Ref 4). *Note:* Asperities, their shapes, sizes, and mechanical properties are the basis for developing many theoretical models for friction, lubrication, and wear behavior.
- **asperity**
  - In tribology, a protuberance in the small-scale topographical irregularities of a solid surface (Ref 2).
- **ASTM viscosity-temperature equation**
  - The equation relating kinematic viscosity (v) with temperature according to:

$$\log \log (v + 0.6) = m \log T + C$$

  - where v is the kinematic viscosity in centistokes, T is the absolute temperature, m is the ASTM slope (slope of the temperature-viscosity curve), and C is a constant that depends on the lubricant (Ref 1m).
- **atomic wear**
  - Wear between two contacting surfaces in relative motion attributed to migration of individual atoms from one surface to the other (Ref 1).
- **attenuation period**
  - See preferred term deceleration period .
- **attitude (attitude angle)**
  - In a bearing, the angular position of the line joining the center of the journal to that of the bearing bore, relative to the direction of loading (Ref 1m).
- **attrition**
  - Removal of small fragments of surface material during sliding contact (Ref 1).
- **average erosion rate**
  - The cumulative erosion divided by the corresponding cumulative exposure duration, that is, the slope of a line from the origin to a specified point on the cumulative erosion-time curve (Ref 2).
- **axial load bearing**
  - See thrust bearing .
- **axial seal**
  - See face seal .
- **B**
- **B_{10}-life**
  - See rating life .
- **Babbitt metal**
  - A nonferrous bearing alloy originated by Isaac Babbitt in 1839. Currently, the term includes several tin-base alloys consisting mainly of various amounts of copper, antimony, tin, and lead. Lead-base Babbitt metals are also used (Ref 1).
- **back ring**
  - A split or multisegment ring in a circumferential seal assembly used for restricting axial leakage flow (Ref 4m).
- **back-to-back ring seal**
  - An adaptation of the simple ring seal that employs two identical elements loaded axially by a spring placed between the rings. The spring forces the elements against mating rings on either side (Ref 4).
- **backing**
  - In plain bearings, the part of the bearing to which the bearing alloy is attached, normally by a metallurgical bond (Ref 1m).
- **ball bearing**

- A rolling-element bearing in which the rolling elements are spherical.
- **ball complement**
  - The number of balls contained in a ball bearing (Ref 1).
- **ball indented bearing**
  - A bearing with surface indentations serving as lubricant reservoirs (Ref 1).
- **basic dynamic load capacity**
  - (of a bearing). The radial load that a rolling-element bearing can support for a rating life of one million revolutions (500 h at $33\frac{1}{3}$ rpm) (Ref 1m). See also basic load rating .
- **basic load rating**
  - (*C*). The radial load that a ball bearing can withstand for one million revolutions of the inner ring. *Note:* The value of the basic load rating depends on bearing type, bearing geometry, accuracy of fabrication, and bearing material (Ref 6m). See also basic dynamic load capacity and dynamic load .
- **basic static load rating**
  - (of a bearing). A load that, if exceeded on a nonrotating rolling-element bearing, produces a total permanent deformation of rolling element and race at the most heavily stressed contact point of 0.0001 times the ball or roller diameter of greater (Ref 1m).
- **bath lubrication**
  - See flood lubrication .
- **bearing**
  - A support or guide by means of which a moving part is located with respect to other parts of a mechanism (Ref 1).
- **bearing area**
  - (1) The projected bearing or load-carrying area when viewed in the direction of the load (Ref 1). *Note:* Sometimes used as a synonym for real area of contact (this usage is not recommended). (2) The sum of the horizontal intercepts of a surface profile at a given level (Ref 1).
- **bearing bronzes**
  - Bronzes used for bearing applications. Two common types of bearing bronzes are copper-base alloys containing 5 to 20 wt% tin and a small amount of phosphorus (phosphor bronzes) and copper-base alloys containing up to 10 wt% tin and up to 30 wt% lead (leaded bronzes) (Ref 1m).
- **bearing characteristic number**
  - A dimensionless number that is used to evaluate the operating conditions of plain bearings (Ref 1). See also capacity number and Sommerfeld number .
- **bearing fraction**
  - The ratio of the bearing area to a reference length (Ref 1).
- **Beilby layer**
  - The altered surface layer formed on a crystalline solid during a wear process or by mechanical polishing that, according to a theory by Sir George Beilby, consists of a material in an amorphous state. *Note:* It is now generally accepted that an amorphous layer is not formed at a surface except possibly in some special cases. Depending on the polishing conditions, the surface layer may be a complex mixture of embedded polishing compound, reaction products, and plastically deformed and fractured surface material. In the context of tribology, the damaged or otherwise altered surface layer resulting from wear is often referred to as the Beilby layer without any implication as to its actual structure or nature (Ref 2).
- **bellows seal**
  - A type of mechanical seal that utilizes a bellows for providing secondary sealing (Ref 4).
- **bidirectional seal**
  - A seal that is designated to seal equally well when the pressure is applied from either direction (Ref 4).
- **big-end bearing**
  - A bearing at the larger (crankshaft) end of a connecting rod in an engine. Also known as bottom-end bearing , crankpin bearing , and large-end bearing (Ref 1m). See also little-end bearing .
- **bimetal bearing**
  - A bearing consisting of two layers. *Note:* Bimetal bearings are usually made with a layer of bearing alloy on a bronze or steel backing (Ref 1).
- **birotational seal**

- A seal that is designed for applications in which a shaft rotation is in either direction (Ref 4).
- **Bingham solid**
  - An idealized form of solid that begins to flow appreciably only when a certain stress, called the yield stress or yield point, has been exceeded. The solid subsequently flows at a rate proportional to the difference between the applied stress and this yield stress. *Note:* Many greases can be regarded as Bingham solids (Ref 1).
- **bleeding**
  - Separation of oil (or other fluid) from a grease (Ref 1).
- **blending**
  - The process of mixing mineral oils to obtain the desired consistency. *Note:* Blending should be contrasted with compounding, which utilizes additives (Ref 1m).
- **block grease**
  - A grease that is sufficiently hard to retain its shape in block or stick form (Ref 1).
- **blown oil**
  - Fatty oil that is artificially thickened by blowing air through it (Ref 1).
- **body**
  - A loosely used term designating viscosity or consistency. *Note:* Use of this term is not recommended (Ref 1m).
- **bonded film lubricant**
  - See bonded solid lubricant .
- **bonded solid lubricant**
  - A solid lubricant dispersed in a continuous matrix of a binder, or attached to a surface by an adhesive material (Ref 1).
- **bone oil**
  - A fatty oil obtained by dry distillation of bones (Ref 1).
- **bore seal**
  - A device in which the outside diameter mates with a bore surface to provide sealing between the two surfaces (Ref 4m).
- **bottom-end bearing**
  - See big-end bearing .
- **boundary lubricant**
  - A lubricant suitable for use in boundary lubrication conditions. *Note:* Fatty acids and soaps are commonly used (Ref 1.)
- **boundary lubrication**
  - A condition of lubrication in which the friction and wear between two surfaces in relative motion are determined by the properties of the surfaces and by the properties of the lubricant other than bulk viscosity. *Note:* Many circumstances that at one time were referred to as boundary lubrication may be elastohydrodynamic (Ref 1). See also elastohydrodynamic lubrication , extreme-pressure lubrication , and thin-film lubrication .
- **Brale indenter**
  - A conical 120° diamond indenter with a conical tip (a 0.2 mm tip radius is typical) used in certain types of Rockwell and scratch hardness tests.



Brale indenter

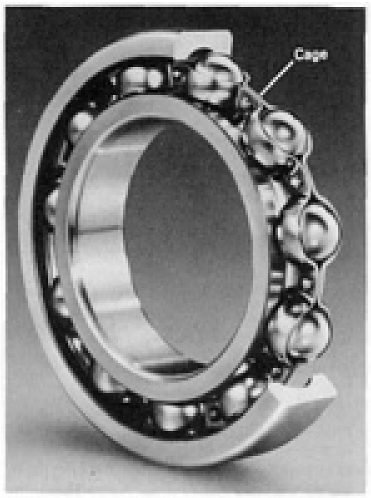
- **break-away torque**
  - See starting torque .
- **break in**
  - (verb). To operate a newly installed bearing, seal, or other tribocomponent in such a manner as to condition its surface(s) for improved functional operation. See also run in (verb).
- **break-in**
  - (noun). See running-in .
- **bright stock**
  - High-viscosity mineral oils that remain after vacuum distillation of crude oil (Ref 1).
- **Brinell hardness test**
  - Invented by Swedish engineer J.A. Brinell and gaining widespread acceptance about 1900, it is a measure of penetration hardness obtained by forcing a hard sphere of diameter (*D*) (10 mm typically) into a surface under a load (*P*) so as to produce an impression of diameter (*d*) in the surface of the testpiece. The Brinell hardness number (HB) is a measure of the average indentation pressure calculated as follows:

$$\mathrm{HB} = \frac{P}{(\pi D/2)[D - \sqrt{(D^2 - d^2)}]}$$

- **Brinelling**
  - (1) Indentation of the surface of a solid body by repeated local impact or impacts, or static overload. *Note:* Brinelling may occur especially in a rolling-element bearing (Ref 1). (2) Damage to a solid bearing surface characterized by one or more plastically formed indentations brought about by overload. *Note:* This term is often applied in the case of rolling-element bearings (Ref 2). See also false Brinelling .
- **bubbly oil**
  - Oil containing bubbles of gas (Ref 1).
- **built-up edge**
  - Material from the workpiece, especially in machining, which is stationary with respect to the tool (Ref 1). See also wedge formation .
- **burning**

- In sliding contacts, the oxidation of a surface due to local heating in an oxidizing environment (Ref 1). See also metallurgical burn .

- **burnish**
  - (1) To alter the original manufactured surface of a sliding or rolling surface to a more polished condition (Ref 1m). (2) To apply a substance to a surface by rubbing.
- **bush bearing**
  - A plain bearing in which the lining is closely fitted into the housing in the form of a bush, usually surfaced with a bearing alloy (Ref 1).
- **C**
- **cage**
  - In a bearing, a device that partly surrounds the rolling elements and travels with them, the main purpose of which is to space the rolling elements in proper relation to each other (Ref 1). See also separator .



Cage in a radial ball bearing (cutaway view)

- **capacity number**
  - (C_n). The product of the Sommerfeld number and the square of the length-to-diameter ratio of a journal bearing (Ref 7).
- **capture efficiency**
  - See collection efficiency .
- **carbonization**
  - A reduction of hydrocarbons, resulting in the formation of carbonaceous residue (Ref 4).
- **case crushing**
  - A term used to denote longitudinal gouges arising from fracture in case-hardened gears (Ref 1m).
- **catastrophic period**
  - In cavitation or liquid impingement erosion, a stage during which the erosion rate increases so dramatically that continued exposure threatens or causes gross disintegration of the exposed surface. *Note:* This stage is not inevitable; it is observed most commonly with some brittle materials. When it does occur, it may begin during any stage of the more common erosion rate-time pattern (Ref 2m).
- **catastrophic wear**
  - Sudden surface damage, deterioration, or change of shape caused by wear to such an extent that the life of the part is appreciably shortened or action is impaired (Ref 1).
- **catchment efficiency**
  - See collection efficiency .
- **cavitating disk apparatus**
  - A flow cavitation test device in which cavitating wakes are produced by holes in, or protuberances on, a disk rotating within a liquid-filled chamber. *Note:* Erosion test specimens are

attached flush with the surface of the disk at the location where the bubbles are presumed to collapse (Ref 2m).

- **cavitation**
  - The formation and collapse, within a liquid, of cavities or bubbles that contain vapor or gas or both. *Notes:* In general, cavitation originates from a decrease in the static pressure in the liquid. It is distinguished in this way from boiling, which originates from an increase in the liquid temperature. There are certain situations where it may be difficult to make a clear distinction between cavitation and boiling, and the more general definition that is given here is therefore to be preferred. In order to erode a solid surface by cavitation, it is necessary for the cavitation bubbles to collapse on or close to that surface (Ref 2).
- **cavitation cloud**
  - A collection of a large number of cavitation bubbles. *Note:* The bubbles in a cloud are small, typically less than 1 mm in cross section (Ref 2m).
- **cavitation erosion**
  - (1) Progressive loss of original material from a solid surface due to continued exposure to cavitation (Ref 2). (2) Wear of a solid body moving relatively to a liquid in a region of collapsing vapor bubbles that cause local high-impact pressures or temperatures. *Notes:* It is recommended that the term cavitation erosion should be used in preference to cavitation to describe the wear process; cavitation refers only to the formation and collapse of cavities in the liquid. Cavitation erosion may also be intensified by chemical action (Ref 1).
- **cavitation number**
  - (σ). A dimensionless number that measures the tendency for cavitation to occur in a flowing stream of liquid, and that is computed from the equation:

$$\sigma = (P_0 - P_v)/\tfrac{1}{2}\rho V_0^2$$

  - where P_v is the vapor pressure, P_o is the static pressure in the stream in an undisturbed state, V_o is the undisturbed stream velocity, and ρ is the liquid density. *Note:* The cavitation number and the net positive suction head (NPSH) are related by the following equation:

$$\text{NPSH} = (\sigma + 1)\, V_0^2/2g$$

  - where g is the acceleration due to gravity (Ref 2).
- **cavitation tunnel**
  - A flow cavitation test facility in which liquid is pumped through a pipe or tunnel, and cavitation is induced in a test section by conducting the flow through a constriction, or around an obstacle, or a combination of these (Ref 2).
- **centane number**
  - A measure of the ignition quality of a fuel or petroleum product with reference to normal centane high-ignition quality fuel with an arbitrary number of 100 (Ref 5).
- **chafing**
  - Repeated rubbing between two solid bodies that can result in surface damage and/or wear.
- **channeling**
  - (1) The tendency of a grease or viscous oil to form air channels in a bearing or gear system, resulting in an incomplete lubricant film (Ref 1). (2) The tendency of a grease to form a channel by working down in a bearing or distribution system, leaving shoulders to act as a reservoir and seal (Ref 1).
- **chatter**
  - Elastic vibrations resulting from frictional or other instability (Ref 1).
- **checking**
  - See craze cracking .
- **chemical conversion coating**
  - A coating produced by a chemical or electrochemical treatment of a metallic surface resulting in a superficial layer containing compounds of the metal. Such coatings are usually pretreatments

onto which fluid or solid lubricants may be applied, but which may themselves have lubricating properties (Ref 1).

- **chemical wear**
  - See corrosive wear .
- **chlorinated lubricant**
  - A lubricant containing a chlorine compound that reacts with a rubbing surface at elevated temperatures to protect it from sliding damage (Ref 1). See also extreme-pressure lubricant , sulfochlorinated lubricant , and sulfurized lubricant .
- **circular-step bearing**
  - A flat circular hydrostatic bearing with a central circular recess (Ref 1). See also step bearing .
- **cladding**
  - A layer of material, usually metallic, that is mechanically or metallurgically bonded to a substrate. *Note:* Cladding may be bonded to the substrate by any of several processes, such as roll-cladding and explosive forming.
- **clearance ratio**
  - In a bearing, the ratio of radial clearance to shaft radius (Ref 1).
- **cloud point**
  - The temperature at which a wax cloud first appears on cooling a mineral oil under specified conditions (Ref 1).
- **cocoa**
  - In fretting wear, a powdery form of debris, usually consisting of iron oxides, that is expelled from a ferrous metal joint near the location where fretting wear is occurring. Also known as red mud .
- **coefficient of adhesion**
  - (1) The ratio of the normal force required to separate two bodies to the normal load with which they were previously placed together. Used in studies with denuded surfaces (Ref 1). (2) In railway engineering, sometimes used to signify the coefficient of (limiting) static friction (Ref 1).
- **coefficient of friction**
  - In tribology, the dimensionless ratio of the friction force (F) between two bodies to the normal force (N) pressing these bodies together (Ref 2):

$$\mu (\text{or } f) = (F/N)$$

  - *Notes:* The friction force is often proportional to the normal force when the surfaces rub together under dry or boundary-lubricated conditions, but not when the surfaces are separated by a full fluid film, as in hydrodynamic lubrication, or by a solid-film lubricant. The friction force and normal force are not proportional for denuded surfaces or for single contacts between elastically deformed bodies. Two symbols, f and μ, are commonly used for designating the coefficient of friction, but subscripts may be added to further specify static or kinetic friction conditions (Ref 1m).
- **coefficient of wear**
  - See Archard wear law , wear coefficient , wear constant , and wear factor .
- **cold test**
  - A test in which the pour point of an oil is determined (Ref 1).
- **collar oiler**
  - A collar on a shaft that extends into the oil reservoir and carries oil into a bearing as the shaft rotates. Wipers are usually provided to direct the oil into the bearing (Ref 1).
- **collection efficiency**
  - The cross-sectional area of undisturbed fluid containing particles that will ultimately impinge on a given solid surface, divided by the projected area of the solid surface (Ref 2m). Also known as collision efficiency , capture efficiency , catchment efficiency , and impaction ratio .
- **collision efficiency**
  - See collection efficiency .
- **compatibility (frictional)**
  - In tribology, materials that exhibit good sliding behavior, including resistance to adhesive wear, are termed frictionally compatible. *Note:* Under some conditions materials that are not normally

considered compatible in the metallurgical sense (for example, silver and iron) may be very compatible in the frictional sense (Ref 1m).

- **compatibility (lubricant)**
  - In tribology, a measure of the degree to which lubricants or lubricant components can be mixed without harmful effects such as formation of deposits (Ref 1).
- **compatibility (metallurgical)**
  - A measure of the extent to which materials are mutually soluble in the solid state (Ref 1).
- **compensation**
  - In a hydrostatic bearing, the use of flow resistances between the supply and the entry to the bearing (Ref 1).
- **composite bearing material**
  - A solid material composed of a continuous or particulate solid lubricant dispersed throughout a load-bearing matrix to provide continuous replenishment of solid lubricant films as wear occurs, and effective heat transfer from the friction surface (Ref 1). *Note:* Composite bearing materials need not only be self-lubricating, but can also be used for low wear, good frictional heat dissipation, or controlled frictional response (for example, brake materials). Examples of composite materials are metal-matrix composites, laminated composites, filament-wound composites, and fiber-mineral-metal-filled composites (Ref 8).
- **compressibility number**
  - A dimensionless group used in gas bearing calculations. *Note:* For thrust bearings, the compressibility number relates viscosity (η), velocity (v), pressure (P_a), and clearance (h_o) as follows:

$$\frac{\eta v}{P_a h_0^2}$$

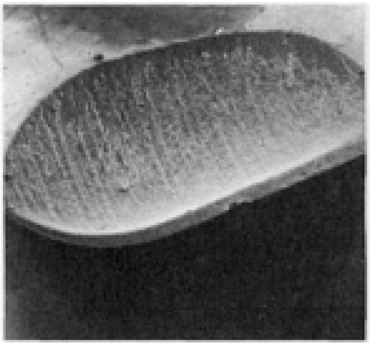
  - For journal bearings, the compressibility number relates to viscosity (η), rotational speed (U), pressure (P_o), radius (r), and clearance (c) as follows (Ref 1):

$$\frac{\eta U r}{P_0 c^2}$$

- **compression set**
  - In seals, the difference between the thickness of a gasket of static seal before the seal is compressed and after it is released from compression. *Note:* Compression set is normally expressed as a percentage of the total compression (Ref 4m).
- **cone resistance value**
  - (CRV). A measure of the yield stress of a grease, obtained by static indentation with a cone. *Note:* The equilibrium depth of penetration is measured, not the penetration in a given time, which is the penetration value (Ref 1). See also penetration (of a grease) .
- **conformability**
  - In tribology, that quality of a plain bearing material that allows it to adjust itself to shaft deflections and minor misalignments by deformation or by wearing away of bearing material without producing operating difficulties (Ref 1).
- **conformal surfaces**
  - Surfaces whose centers of curvature are on the same side of the interface. *Note:* In wear testing, it refers to the case where the curvature of both specimens matches such that the nominal contact area during the testing remains approximately constant (Ref 1m). Contrast with counterformal surfaces .
- **consistency**
  - An imprecise measure of the degree to which a grease resists deformation under the application of a force (Ref 1). See also cone resistance value and penetration hardness number .
- **constriction resistance**

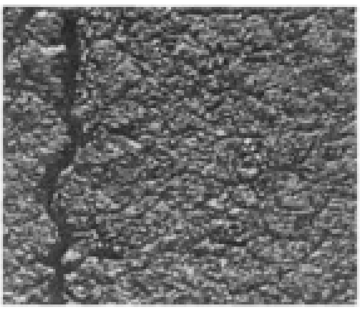
- In electrical contact theory, the resistance that arises from the constriction of current flow lines in order to pass through small areas of contact (a-spots) at the interface of two contacting bodies (Ref 1m). See also a-spot , contact resistance , and film resistance .

- **contact angle**
  - In lubrication, the angle at which the surface of a liquid drop meets the surface of a solid on which it is placed (Ref 1).
- **contact angle**
  - (in a bearing). See angle of contact .
- **contact lubrication**
  - A little-used term relating to the conditions of lubrication obtained with solid lubricant powders rubbed into a surface. *Note:* It is recommended that this term should not be used (Ref 1).
- **contact resistance**
  - The electrical resistance between two contacting bodies, which is the sum of the constriction resistance and the film resistance (Ref 1).
- **contact stress**
  - Stress that results near the surfaces of two contacting solid bodies when they are placed against one another under a nonzero normal force. *Note:* This term is not sufficiently precise because it does not indicate the type of stress, although common usage usually implies elastic or Hertz stress.
- **contacting ring seal**
  - A type of circumferential seal that utilizes a ring spring-loaded radially against a shaft. The ring is either gapped or segmented, in order to have radial flexibility. The seal has overlapping joints for blocking leakage at the gaps. An axial spring load seats the ring against the wall of its containing cartridge (Ref 4m).
- **conversion coating**
  - See chemical conversion coating .
- **corrosive wear**
  - A wear process in which chemical or electrochemical reaction with the environment predominates (Ref 1). See also oxidative wear .
- **Coulomb friction**
  - A term used to indicate that the frictional force is proportional to the normal load (Ref 1).
- **Coulomb's laws**
  - See Amontons' laws .
- **counterformal surfaces**
  - Surfaces whose centers of curvature are on the opposite sides of the interface, as in rolling-element bearings or gear teeth. *Note:* In wear testing, this term is sometimes used to indicate that the test specimen surfaces are not conformal (for example, with a sphere-on-flat or flat block-on-rotating ring configuration). In such cases, the nominal contact area of at least one of the testpiece surfaces increases as the amount of wear increases (Ref 1m). Contrast with conformal surfaces .
- **cracking**
  - In lubrication technology, that process of converting unwanted long-chain hydrocarbons to shorter molecules by thermal or catalytic action (Ref 1).
- **crankpin bearing**
  - See big-end bearing .
- **crater wear**
  - The wear that occurs on the rake face of a cutting tool due to contact with the material in the chip that is sliding along that face.



Crater wear on a cemented carbide tool. 15×

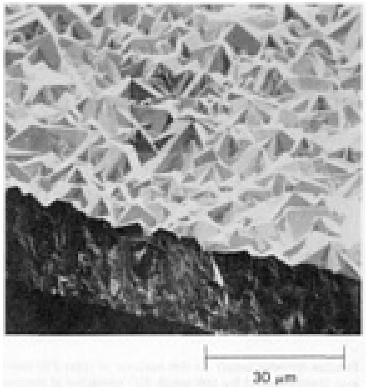
- **craze cracking**
  - Irregular surface cracking associated with thermal cycling. *Note:* This term is used more in the United Kingdom than in the United States, where the term checking is used instead (Ref 1m).



Craze cracking on the outer surface of a stainless steel tube. ~4×

- **creep**
  - (1) Time-dependent deformation. *Note:* In tribology, the deformation may occur if a static or moving contact is held under load at such conditions that one or more of the materials in contact experiences time-dependent deformation. Creep is a problem in certain polymeric bearing materials. (2) Small relative tangential displacement in a contacting area at an interface, when the remainder of the interface in the contacting area is not relatively displaced tangentially (Ref 3). Also known as microslip .
- **creep ratio**
  - In a ball bearing, the ratio of the creep velocity to sweep velocity (Ref 1m). See also creep (2).
- **crush**
  - In a split-journal bearing, the amount by which a bearing half extends above the horizontal split of the bore before it is assembled (Ref 1m). Also known as nip in the United Kingdom.
- **cumulative erosion-time curve**
  - A plot of cumulative erosion versus cumulative exposure duration, usually obtained by periodic interruption of the erosion test and weighing of the specimen. *Note:* This is the primary record of an erosion test used to derive other characteristics such as incubation period, maximum erosion rate, terminal erosion rate, and the erosion rate-time curve (Ref 2m).
- **cut**
  - In lubricant technology, a product or fraction obtained by distillation within a specified temperature range 1
- **cutting wear**
  - See abrasive wear
- **D**
- **debris**
  - See wear debris .

- **deceleration period**
  - In cavitation or impingement erosion, the stage following the acceleration period or the maximum rate period (if any), during which the erosion rate has an overall decreasing trend although fluctuations may be superimposed on it (Ref 2).
- **deformability**
  - See conformability .
- **deformation wear**
  - Sliding wear involving plastic deformation of the wearing surface. *Note:* Many forms of wear involve plastic deformation, so this term is imprecise and should not be used.
- **delamination wear**
  - A wear process in which thin layers of material are formed and removed from the wear surface. *Note:* A "delamination theory of wear" proposed by N.P. Suh in the early 1970s involves the nucleation and propagation of cracks so as to form lamellar wear particles; however, there are other ways to form lamellar wear particles (for example, by the loss of transfer layer fragments), and the term delamination wear should not be used unless further clarification of the context of usage is provided.
- **detergent additive**
  - In lubrication technology, a surface-active additive that helps to keep solid particles suspended in an oil (Ref 1m).
- **detergent oil**
  - A heavy-duty oil containing a detergent additive. *Note:* Detergent oils are used mainly in combustion engines (Ref 1).
- **detritus**
  - See wear debris .
- **diamond film**
  - A carbon-composed film, usually deposited by chemical vapor deposition or related process, that has the following three characteristics: (1) a crystalline morphology that can be visually discerned by optical microscopy, (2) a single-phase crystalline structure identifiable by x-ray and/or electron diffraction, and (3) a Raman spectrum typical for crystalline diamond. *Note:* The sharpness of the sp^3 carbon-carbon bonding peak (wave-number 1332 cm^{-1}) is often used to determine the perfection of the film (Ref 9m). See also diamondlike film .



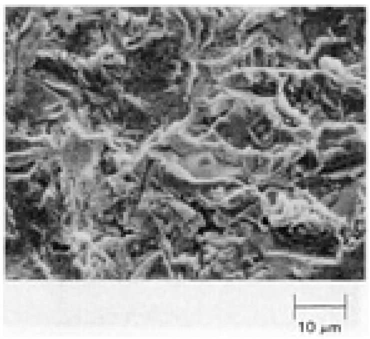
Diamond film grown on silicon. Courtesy of R. Clausing, ORNL

- **diamondlike film**
  - A hard, noncrystalline carbon film, usually grown by chemical vapor deposition or related techniques, that contains predominantly sp^2 carbon-carbon bonds. *Note:* In Raman spectroscopy, the absence of a sharp peak at wavenumber 1332 cm^{-1} and a broad peak at 1500 to 1600 cm^{-1} is characteristic of diamondlike films (Ref 9m). See also diamond film .
- **dilatant**
  - A reversible increase in viscosity with increasing shear stress (Ref 1). Compare with pseudoplastic behavior , rheopectic material , and thixotropy .
- **dirt content**

- A measure of the size and concentration of foreign particles present in a lubricant. *Note:* Dirt content is usually reported as the number of particles per cubic centimeter, for specified particle sizes (Ref 5).
- **disk machine**
  - In tribology, a testing machine for rolling or rolling/sliding contact in which two disk-shaped rollers, with parallel axes of rotation, make tangential contact on their circumferences as they move relative to one another. *Note:* One or both disks may be crowned on the rolling-contact surface. See also Amsler wear machine .
- **dispersant additive**
  - In lubrication technology, an additive capable of dispersing cold oil sludge (Ref 1m).
- **dispersant oil**
  - A heavy-duty oil containing a dispersant additive (Ref 1).
- **distributed impact test**
  - In impingement erosion testing, an apparatus or method that produces a spatial distribution of impacts by liquid or solid bodies over an exposed surface of a specimen. *Note:* Examples of such tests are those employing liquid sprays or simulated rainfields. If the impacts are distributed uniformly over the surface, the term uniformly distributed impact test may be used (Ref 2).
- **DN value**
  - The product of bearing bore diameter in millimeters and speed in revolutions per minute (Ref 5).
- **drawing compound**
  - In metalworking, a lubricant having extreme-pressure properties (Ref 1m). See also extreme-pressure lubricant .
- **drip feed (drop feed) lubrication**
  - A system of lubrication in which the lubricant is supplied to the bearing surfaces in the form of drops at regular intervals (Ref 1m).
- **drop (dropping) point**
  - The temperature at which a drop falls from a grease through a specified orifice. *Note:* The drop point does not necessarily represent the maximum operating temperature of a grease (Ref 1m).
- **droplet erosion**
  - Erosive wear caused by the impingement of liquid droplets on a solid surface. See also erosion (erosive) wear .
- **dry-film lubrication**
  - Lubrication that involves the application of a thin film of solid lubricant to the surface or surfaces to be lubricated.
- **dry friction**
  - Friction that occurs between two bodies in the absence of lubrication. *Note:* This term is inaccurate because it historically implies that there is no intentionally applied lubrication, when in fact solid lubrication conditions can be considered "dry". Therefore, this term should not be used.
- **dry lubricant**
  - See solid lubricant . *Note:* It has been suggested that this term should not be used as a synonym for solid lubricant because some solid lubricants perform better in the presence of moisture (for example, graphite). Instead, it should refer to lubricants that function in low-moisture environments (Ref 10).
- **dry-running**
  - In seals, running without liquid present at the seal surface (Ref 4).
- **dry sand-rubber wheel test**
  - In wear testing, a term used to describe a standard abrasive wear testing method in which a stream of dry quartz sand is passed between a rotating rubber wheel and a stationary test coupon that is held against it under specified normal force. Further information can be found in ASTM Standard Test Method G 65.
- **dry sliding water**
  - Sliding wear in which there is no intentional lubricant or moisture introduced into the contact area. *Note:* Species such as oxides and other films, or adsorbed species that are initially present or that form during sliding contact, may lubricate the contact; however, the contact is often referred to as being "unlubricated". This imprecise term is not usually used when solid lubricants are introduced even though they could be considered to be dry. See also unlubricated sliding .
- **duplex alloys**

- Bearing alloys consisting of two phases, one much softer than the other (Ref 1).
- **durometer reading**
  - An index that is used for ranking the relative hardness of elastomers (Ref 4). *Note:* The durometer hardness test involves forcing a 30° tapered indenter into the surface of the specimen using calibrated loading springs. A dial gage indicates the depth of penetration in durometer numbers, which are directly proportional to the load on the spring.
- **dusting**
  - A phenomenon, usually affecting carbon-base electrical motor brushes or other current-carrying contacts, wherein at low relative humidity or high applied current density, a powdery "dust" is produced during operation.
- **duty**
  - The specification giving the load, ambient temperature, and speed under which surfaces are required to move (Ref 1).
- **duty parameter**
  - See capacity number .
- **dynamic friction**
  - See kinetic friction .
- **dynamic load**
  - An imposed force that is in motion, that is, one that may vary in magnitude, sense, and direction (Ref 11).
- **dynamic seal**
  - A seal that has rotating, oscillating, or reciprocating motion between its components, as opposed to stationary-type seal such as a gasket (Ref 4).
- **dynamic viscosity**
  - See viscosity .
- **E**
- **eccentricity**
  - In journal bearings, the radial displacement of the journal center from the center of the bearing liner (Ref 1m).
- **eccentricity ratio**
  - In a bearing, the ratio of the eccentricity to the radial clearance (Ref 1).
- **effective leakage area**
  - The orifice flow area that will result in the same calculated flow for a given pressure drop as is measured for the seal in question. *Note:* This concept is useful when comparing the leakage performance of seals of different sizes and designs, and of seals operating under different conditions (Ref 4m).
- **elastic compliance**
  - A condition under which two bodies in contact, which are subjected to a force, undergo small elastic displacement without slip (Ref 1).
- **elastohydrodynamic lubrication**
  - A condition of lubrication in which the friction and film thickness between two bodies in relative motion are determined by the elastic properties of the bodies, in combination with the viscous properties of the lubricant at the prevailing pressure, temperature, and rate of shear (Ref 1). See also boundary lubrication , plastohydrodynamic lubrication , and thin-film lubrication .
- **electrical pitting**
  - The formation of surface cavities by removal of metal as a result of an electrical discharge across an interface (Ref 1).
- **electrocorrosive wear**
  - Wear to a solid surface which is accelerated by the presence of a corrosion-inducing electrical potential across the contact interface. *Note:* This process is usually associated with wear in the presence of a liquid electrolyte in the interface. However, moisture from the air can also facilitate this type of wear when a galvanic wear couple exists and the contacting materials are sufficiently reactive.
- **elliptical bearing**
  - See lemon bearing (elliptical bearing) .
- **embeddability**
  - The ability of a bearing material to embed harmful foreign particles and reduce their tendency to cause scoring or abrasion (Ref 1).

- **emulsion**
  - A dispersion of globules of one liquid in a second immiscible liquid (for example, oil in water). *Notes:* Lubricant emulsions are usually stabilized by a suitable agent. The stability of an emulsion increases with decreasing diameter of the droplets. Typical lubricant emulsions are prepared from oil and water (Ref 1).
- **emulsion inversion**
  - An emulsion is said to invert when, for example, a water-in-oil emulsion changes to an oil-in-water emulsion (Ref 1).
- **end seal**
  - See face seal .
- **engine oil**
  - An oil used to lubricate an internal combustion engine (Ref 1).
- **Engler viscosity**
  - A commercial measure of viscosity expressed as the ratio between the time in seconds required for 200 cm^3 of a fluid to flow through the orifice of an Engler viscometer at a given temperature under specified conditions and the time required for 200 cm^3 of distilled water at 20 °C to flow through the orifice under the same conditions. *Note:* It is recommended that standard viscosity units should be used (Ref 1).
- **entraining velocity**
  - The velocity of a liquid at which bubbles of gas are carried along in the stream (Ref 1).
- **EP lubricant**
  - See extreme-pressure lubricant .
- **equivalent radial load**
  - The level of constant radial load on a rolling-element bearing that, when the bearing is stationary with respect to the outer race, will produce the same rating life as a given combination of radial and thrust loads under the same conditions of operation (Ref 1).
- **erosion (erosive wear)**
  - (1) Loss of material from a solid surface due to relative motion in contact with a fluid that contains solid particles. *Note:* Erosion in which the relative motion of particles is nearly parallel to the solid surface is called abrasive erosion . Erosion in which the relative motion of the solid particles is nearly normal to the solid surface is called impingement erosion or impact erosion (Ref 1). (2) Progressive loss of original material from a solid surface due to mechanical interaction between that surface and a fluid, a multicomponent fluid, and impinging liquid, or solid particles. *Note:* Because of the broad scope of this term, it is recommended that it normally be qualified to indicate the relevant mechanism or context, for example, impingement erosion , abrasive erosion , and so forth (Ref 2). See also cavitation erosion and electrical pitting .



Erosion (erosive wear) on the surface of type 310 stainless steel eroded by 100 mesh SiC particles at normal incidence and 40 m/s impingement velocity. Courtesy of L.K. Ives, NIST

- **erosion-corrosion**
  - A conjoint action involving corrosion and erosion in the presence of a corrosive substance (Ref 2).
- **erosion rate**

- Any determination of the rate of loss of material (erosion) with exposure duration. *Note:* In certain contexts (for example, ASTM erosion tests), it is given by the slope of the cumulative erosion-time curve (Ref 2m).

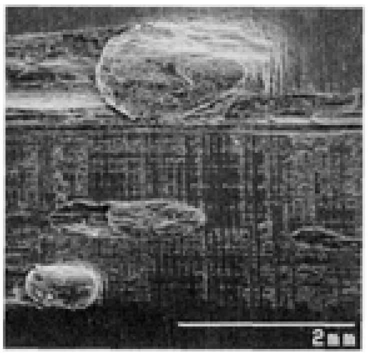
- **erosion rate-time curve**
  - A plot of instantaneous erosion rate versus exposure duration, usually obtained by numerical or graphical differentiation of the cumulative erosion-time curve (Ref 2).
- **erosivity**
  - The characteristic of a collection of particles, liquid stream, or a slurry that expresses its tendency to cause erosive wear when forced against a solid surface under relative motion.
- **excrescence**
  - A term used by some Russian tribologists (in English) describing micro-extrusions on friction surfaces that lead to localized welding. *Note:* This term is not recommended (Ref 1).
- **externally pressurized seal**
  - A seal that operates on a thin film at the interface with the mating surface. *Note:* The film is formed by high-pressure fluid that is brought to the interface at some mid-dam location and that is at a pressure equal to, or higher than, the up-stream seal pressure (Ref 4m). See also hydrostatic seal .
- **extreme-pressure lubricant**
  - A lubricant that imparts increased load-carrying capacity to rubbing surfaces under severe operating conditions. *Note:* Extreme-pressure lubricants usually contain sulfur, halogens, or phosphorus. The term antiscuffing lubricant has been suggested as a replacement for extreme-pressure lubricant (Ref 1m).
- **extreme-pressure lubrication**
  - A condition of lubrication in which the friction and wear between two surfaces in relative motion depend upon the reaction of the lubricant with a rubbing surface at elevated temperature (Ref 1).
- **F**
- **face pressure**
  - The face load divided by the contacting area of the sealing lip. *Notes:* The face load is the sum of the pneumatic or hydraulic force and the spring force. For lip seals and packings, the face load also includes the interference load (Ref 4m).
- **face seal**
  - A device that prevents the leakage of fluids along rotating shafts. *Note:* Sealing is accomplished by a stationary primary-seal ring bearing against the face of a mating ring mounted on a shaft. Axial pressure maintains the contact between seal ring and mating ring (Ref 4m).
- **false Brinelling**
  - (1) Damage to a solid bearing surface characterized by indentations not caused by plastic deformation resulting from overload, but thought to be due to other causes such as fretting corrosion (Ref 2). (2) Local spots appearing when the protective film on a metal is broken continually by repeated impacts, usually in the presence of corrosive agents. *Notes:* The appearance is generally similar to that produced by Brinelling but corrosion products are usually visible. It may result from fretting corrosion. This term should be avoided when a more precise description is possible (Ref 1). False Brinelling (race fretting) can be distinguished from true Brinelling because in false Brinelling, surface material is removed so that original finishing marks are removed. The borders of a false Brinell mark are sharply defined, whereas a dent caused by a rolling element does not have sharp edges and the finishing marks are visible in the bottom of the dent (Ref 8).
- **fat**
  - An organic ester, the product of a reaction between a fatty acid and glycerol. *Note:* Fat can be of animal or vegetable materials or can be made synthetically (Ref 1).
- **fatigue wear**
  - (1) Removal of particles detached by fatigue arising from cyclic stress variations (Ref 1). (2) Wear of a solid surface caused by fracture arising from material fatigue (Ref 2). See also spalling .
- **fatty acid**
  - An organic acid of aliphatic structure originally derived from fats and fatty oils (Ref 1).
- **fatty oil**
  - A fat (glycerol ester) that is liquid at room temperature (Ref 1).
- **feedability**

- The ability of a grease to flow to the suction of a pump (Ref 1).
- **ferrograph**
  - An instrument used to determine the size distribution of wear particles in lubricating oils of mechanical systems (Ref 5). *Note:* The technique relies on the debris being capable of being attracted to a magnet.
- **fiber grease**
  - A type of grease having a pronounced fibrous structure (Ref 1).
- **file hardness**
  - Hardness as determined by the use of a file of standardized hardness on the assumption that a material that cannot be cut with the file is as hard as, or harder than, the file. *Note:* Files covering a range of hardnesses may be employed (Ref 5m).
- **filler**
  - In lubrication, a substance such as lime, talc, mica, and other powders, added to a grease to increase its consistency or to an oil to increase its viscosity (Ref 1).
- **film resistance**
  - The electrical resistance that results from films at contacting surfaces, such as oxides and contaminants, that prevent pure metallic contact (Ref 1). See also constriction resistance and contact resistance .
- **film strength**
  - An imprecise term denoting ability of a surface film to resist rupture by the penetration of asperities during sliding or rolling. *Note:* A high film strength is primarily inferred from a high load-carrying capacity and is seldom directly measured. It is recommended that this term should not be used (Ref 1).
- **film thickness**
  - In a dynamic seal, the distance separating the two surfaces that form the primary seal (Ref 4m).
- **fire point**
  - The temperature at which a material will continue to burn for at least 5 s without the benefit of an outside flame (Ref 5).
- **fixed-land bearing**
  - See fixed-pad bearing .
- **fixed oil**
  - An imprecise term denoting an oil that is difficult to distill without decomposition (Ref 1).
- **fixed-pad bearing**
  - An axial- or radial-load bearing equipped with fixed pads, the surfaces of which are contoured to promote hydrodynamic lubrication (Ref 1).
- **flaking**
  - (1) The removal of material from a surface in the form of flakes or scalelike particles. (2) A form of pitting resulting from fatigue (Ref 12m). See also spalling .
- **flank wear**
  - The loss of relief on the flank of a cutting tool behind the cutting edge due to rubbing contact between the work and the tool during cutting, measured in terms of linear dimension behind the original cutting edge (Ref 5m).
- **flash point**
  - The lowest temperature at which the vapor of a lubricant can be ignited under specified conditions (Ref 1).
- **flash temperature**
  - The maximum local temperature generated at some point in a sliding contact. *Notes:* The flash temperature occurs at areas of real contact due to the frictional heat dissipated at these areas. The duration of the flash temperature is often of the order of a microsecond. The term flash temperature may also mean the average temperature over a restricted contact area (for example, between gear teeth) (Ref 1m).
- **flexible hinge**
  - See flexure pivot bearing .
- **flexure pivot bearing**
  - A type of bearing guiding the moving parts by flexure of an elastic member or members rather than by rolling or sliding. *Note:* Only limited movement is possible with a flexure pivot (Ref 1).
- **floating bearing**
  - A bearing designed or mounted to permit axial displacement between shaft and housing (Ref 1).

- **floating-ring bearing**
  - A type of journal bearing that includes a thin ring between the journal and the bearing. The ring floats and rotates at a fraction of the journal rotational speed (Ref 1m).
- **flock point**
  - A measure of the tendency of a lubricant to precipitate wax or other solids from solution. *Note:* Depending on the test used, the flock point is the temperature required for precipitation, or the time required at a given temperature for precipitation (Ref 5).
- **flood lubrication**
  - A system of lubrication in which the lubricant is supplied in a continuous stream at low pressure and subsequently drains away. Also known as bath lubrication (Ref 1m).
- **flow cavitation**
  - Cavitation caused by a decrease in static pressure induced by changes in the velocity of a flowing liquid. *Note:* Typically this may be caused by flow around an obstacle or through a constriction, or relative to a blade or foil (Ref 2m).
- **fluid bearing**
  - See hydrostatic bearing .
- **fluid erosion**
  - See liquid impingement erosion .
- **fluid friction**
  - Frictional resistance due to the viscous or rheological flow of fluids (Ref 1m).
- **fluidity**
  - The reciprocal of viscosity . *Note:* In the centimeter-gram-second (cgs) system, the unit of fluidity is the rhe, which has units of grams per centimeter second (Ref 5).
- **fluted bearing**
  - A sleeve bearing with oil grooves generally in an axial direction (Ref 1).
- **fluting**
  - (1) In bearings, a form of pitting in which the pits occur in a regular pattern so as to form grooves (Ref 1m). *Notes:* Ridges may occur with or without burnt craters. The general cause involves vibration together with excessive wear or excessive load (Ref 12m). (2) Electric discharge pitting in a rolling-contact bearing subject to vibration (Ref 8).
- **foam inhibitor**
  - A surface-active chemical compound used in minute quantities to prevent or reduce foaming. *Note:* Silicone fluids are frequently used as foam inhibitors (Ref 1).
- **foaming**
  - In tribology, the production and coalescence of gas bubbles on a liquid lubricant surface (Ref 1).
- **foil bearing**
  - A bearing in which the housing is replaced by a flexible foil held under tension against a partition of the journal periphery, lubricant being retained between the journal and the foil (Ref 1).
- **follower plate**
  - A plate fitted to the top surface of a grease dispenser (Ref 1).
- **force-feed lubrication**
  - See pressure lubrication .
- **free rolling**
  - Rolling in which no traction is deliberately applied between a rolling element and another surface (Ref 1).
- **free spread**
  - See nip .
- **fretting**
  - (1) Wear phenomena occurring between two surfaces having oscillatory relative motion of small amplitude. *Note:* Fretting is a term frequently used to include fretting corrosion . This usage is not recommended (Ref 1). (2) Small-amplitude oscillatory motion, usually tangential, between two solid surfaces in contact. *Note:* Here the term fretting refers only to the nature of the motion without reference to wear, corrosion, or other damage that may ensue. The term fretting is often used to denote fretting corrosion and other forms of fretting wear . Usage in this sense is discouraged due to the ambiguity that may arise (Ref 2).
- **fretting corrosion**
  - A form of fretting in which chemical reaction predominates. *Notes:* Fretting corrosion is often characterized by the removal of particles and subsequent formation of oxides, which are often

abrasive and so increase the wear. Fretting corrosion can involve other chemical reaction products, which may not be abrasive (Ref 1).

- **fretting fatigue**
  - The progressive damage to a solid surface that arises from fretting. *Note:* If particles of wear debris are produced, then the term fretting wear may be applied.
- **fretting wear**
  - Wear arising as a result of fretting (2) (Ref 2).
- **friction**
  - The resisting force tangential to the common boundary between two bodies when, under the action of an external force, one body moves or tends to move relative to the surface of the other. *Note:* The term friction is also used, incorrectly, to denote coefficient of friction . It is vague and imprecise unless accompanied by the appropriate modifiers, such as dry friction or kinetic friction (Ref 1m). See also static coefficient of friction .
- **friction coefficient**
  - See coefficient of friction .
- **friction force**
  - The resisting force tangential to the interface between two bodies when, under the action of an external force, one body moves or tends to move relative to the other (Ref 2).
- **friction polymer**
  - An amorphous organic deposit that is produced when certain metals are rubbed together in the presence of organic liquids or gases (Ref 1). *Note:* Friction polymer often forms on moving electrical contacts exposed to industrial environments. The varnishlike film will attenuate or modify transmitted signals (Ref 8).
- **frosting**
  - A form of ball bearing groove damage, appearing as a frosted area, suggestive that surface distress has occurred.
- **full-film lubrication**
  - A type of lubrication wherein the solid surfaces are separated completely by an elastohydrodynamic fluid film. See also elastohydrodynamic lubrication .
- **full journal bearing**
  - A journal bearing that surrounds the journal by a full 360 ° (Ref 1m).
- **G**
- **galling**
  - A severe form of scuffing associated with gross damage to the surfaces or failure (Ref 1). *Note:* Galling has been used in many ways in tribology; therefore, each time it is encountered its meaning must be ascertained from the specific context of the usage. See also scoring and scuffing .



Galling on the surface of type 316 stainless steel rubbed against a button of the same material at a load of ~1000 N. Courtesy of L.K. Ives, NIST

- **gas bearing**
  - A journal or thrust bearing lubricated with gas.
- **gas lubrication**

- A system of lubrication in which the shape and relative motion of the sliding surfaces cause the formation of a gas film having sufficient pressure to separate the surfaces (Ref 1). See also pressurized gas lubrication .

- **gasket**
  - A device, usually made of a deformable material, that is used between two relatively static surfaces to prevent leakage (Ref 4m).
- **gelling agent**
  - See thickener .
- **glaze**
  - In tribology, a ceramic or other hard, smooth surface film produced by sliding (Ref 1).
- **gouging abrasion**
  - A form of high-stress abrasion in which easily observable grooves or gouges are created on the surface (Ref 3m). See also abrasion , abrasive wear , high-stress abrasion , and low-stress abrasion .
- **grease**
  - A lubricant composed of an oil thickened with a soap or other thickener to a semi-solid or solid consistency. *Notes:* A lime-base grease is prepared from lubricating oil and calcium soap. Sodium-, barium-, lithium-, and aluminum-base greases are also used. Greases may contain various additives. The liquid phase may also be a synthetic fluid (Ref 1).
- **guide bearing**
  - A bearing used for positioning a slide, or for axial alignment of a long rotating shaft (Ref 1).
- **gum**
  - In lubrication, a rubberlike, sticky deposit, black or dark brown in color, that results from the oxidation and/or polymerization of fuels and lubricating oils. *Note:* Harder deposit are described as lacquers or varnishes (Ref 1).
- **gutterway**
  - In bearings, a special type of spreader in which the groove is adjacent to the joint (Ref 1m).
- **H**
- **hair grease**
  - A grease containing horse hair or wool fiber (Ref 1).
- **half journal bearing**
  - A journal bearing extending 180° around a journal (Ref 1).
- **hard face**
  - A seal facing of high hardness that is applied to a softer material, such as by flame spraying, plasma spraying, electroplating, nitriding, carburizing, or welding (Ref 4m).
- **hardness**
  - The characteristic of a solid material that expresses its resistance to penetration or abrasion by other bodies. *Note:* Taken by itself, the term hardness is virtually meaningless. To have meaning, it must be expressed either as a relative quantity or as a numerical quantity obtained under specifically described conditions of a hardness testing procedure. Hardness is not a basic property of a solid because it depends on the method of its measurement and the scale used to express it. See also Brinell hardness test , indentation hardness , Knoop (microindentation) hardness number , microindentation hardness number , Rockwell hardness number , and Vickers (microindentation) hardness number .
- **Harrison number**
  - See compressibility number .
- **heat checking**
  - A process in which fine cracks are formed on the surface of a body in sliding contact due to the buildup of excessive frictional heat.
- **heavy-duty oil**
  - An oil that is stable against oxidation, protects bearings from corrosion, and has detergent and dispersant properties. *Note:* Heavy-duty oils are suitable for use in gasoline and diesel engines (Ref 1m).
- **herringbone bearing**
  - Any plain, sleeve, or thrust bearing with herringbone-shaped oil grooves (Ref 1).
- **Hershey number**
  - A dimensionless number that is used to evaluate the performance of bearings. It relates the load per unit width (P), surface velocity (U), and dynamic viscosity (η) as follows:

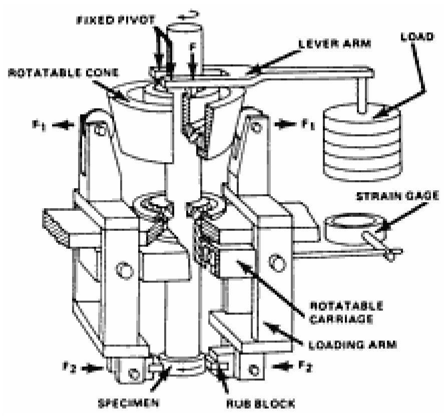
$$\frac{P}{\eta U}$$

- *Note:* This number is normally written as:

$$\frac{ZN}{p}$$

- in which *Z* denotes the dynamic viscosity, *N* the frequency of rotation, and *p* the pressure (Ref 1). See also Ocvirk number , Sommerfeld number , and Stribeck curve .

- **Hertzian contact area**
  - (1) The contact area (also, diameter or radius of contact) between two bodies calculated according to Hertz's equations of elastic deformation (Ref 1m). (2) The apparent area of contact between two nonconforming solid bodies pressed against each other, as calculated from Hertz's equations of elastic deformation (Ref 2).
- **Hertzian contact pressure**
  - (1) The pressure at a contact between two solid bodies calculated according to Hertz's equations of elastic deformation (Ref 1). (2) The magnitude of the pressure at any specified location in a Hertzian contact area, as calculated from Hertz's equations of elastic deformation (Ref 2).
- **high-stress abrasion**
  - A form of abrasion in which relatively large cutting forces are imposed on the particles or protuberances causing the abrasion, and that produces significant cutting and deformation of the wearing surface. *Note:* In metals, high-stress abrasion can result in significant surface strain hardening. This form of abrasion is common in mining and agricultural equipment, and in highly loaded bearings where hard particles are trapped between mating surfaces (Ref 3m). See also low-stress abrasion .
- **highly deformed layer**
  - In tribology, a layer of severely plastically deformed material that results from the shear stresses imposed on that region during sliding contact. See also Beilby layer and white layer .
- **Hohman A-6 wear machine**
  - A widely used type of wear and friction testing machine in which a rotating ring specimen is squeezed between two diametrically opposed rub blocks. *Note:* This design is said to eliminate shaft flexure such as that found in other machines whose load application from the rub block to the ring is from one side only. Block geometry can be changed from flat to conforming or V-block. This type of machine is designed for use with either lubricated or unlubricated specimens.



Hohman A-6 wear machine testing arrangement. Courtesy of Hohman Plating and Manufacturing Company

- **horseshoe thrust bearing**
    - A tilting-pad thrust bearing in which the top pads are omitted, making an incomplete annulus (Ref 1).
- **hydraulic fluid**
    - A fluid used for transmission of hydraulic pressure or action, not necessarily involving lubricant properties. *Note:* Hydraulic fluids can be based on oil, water, or synthetic (fire-resistant) liquids (Ref 1).
- **hydrodynamic lubrication**
    - A system of lubrication in which the shape and relative motion of the sliding surfaces causes the formation of a fluid film that has sufficient pressure to separate the surfaces (Ref 1). See also elastohydrodynamic lubrication and gas lubrication .
- **hydrodynamic seal**
    - A seal that has special geometric features on one of the mating faces. These features are designed to produce interfacial lift, which arises solely from the relative motion between the stationary and rotating portions of the seal (Ref 4).
- **hydrostatic bearing**
    - A bearing in which the solid bodies are separated and supported by a hydrostatic pressure, applied by an external source, to a compressible or incompressible fluid interposed between those bodies.
- **hydrostatic lubrication**
    - A system of lubrication in which the lubricant is supplied under sufficient external pressure to separate the opposing surfaces by a fluid film (Ref 1). See also pressurized gas lubrication .
- **hydrostatic seal**
    - A seal incorporating features that maintain an interfacial film thickness by means of pressure. The pressure is provided either by an external source or by the pressure differential across the seal. The interfacial pressure profile of a seal face is normally speed-dependent; the interfacial pressure profile of the hydrostatic seal is not speed-dependent (Ref 4).
- **hypoid gear lubricant (hypoid oil)**
    - A gear lubricant with extreme-pressure characteristics used in hypoid gears (Ref 1).
- **I**
- **impact velocity**
    - The relative velocity between the surface of a solid body and an impacting liquid or solid particle. *Note:* To describe this velocity completely, it is necessary to specify the direction of motion of the particle relative to the solid surface in addition to the magnitude of the velocity. The following related terms are also in use: (1) absolute impact velocity--the magnitude of the impact velocity, and (2) normal impact velocity--the component of the impact velocity that is perpendicular to the surface of the test solid at the point of impact (Ref 2).
- **impact wear**
    - Wear of a solid surface resulting from repeated collisions between that surface and another solid body. *Note:* The term erosion (erosive) wear is preferred in the case of multiple impacts and when the impacting body or bodies are very small relative to the surface being impacted.
- **impaction ratio**
    - See collection efficiency .
- **impingement**
    - A process resulting in a continuing succession of impacts between liquid or solid particles and a solid surface. *Note:* In preferred usage, impingement also connotes that the impacting particles are smaller than the solid surface, and that the impacts are distributed over the surface or a portion of the surface. If all impacts are superimposed on the same point or zone, then the term repeated impact is preferred (Ref 2m).
- **impingement corrosion**
    - A form of erosion-corrosion generally associated with the impingement of a high-velocity flowing liquid containing air bubbles against a solid surface (Ref 2).
- **impingement erosion**
    - Loss of material from a solid surface due to impingement .
- **impingement umbrella**
    - The partial screening of the surface of a solid specimen subjected to solid impingement that sometimes occurs when some of the solid particles rebound from the surface and impede the motion of other impinging particles (Ref 2).
- **incubation period**

- (1) In cavitation and impingement erosion, the initial stage of the erosion rate-time pattern during which the erosion rate is zero or negligible compared to later stages. (2) In cavitation and impingement erosion, the exposure duration associated with the initial stage of the erosion rate-time pattern during which the erosion rate is zero or negligible compared to later stages. *Note:* Quantitatively, incubation period is sometimes defined as the intercept on the time or exposure axis, of a straight-line extension of the maximum slope portion of the cumulative erosion-time curve (Ref 2m). See also cavitation erosion and impingement erosion .

- **indentation hardness**
  - Resistance of a solid surface to the penetration of a second, usually harder, body under prescribed conditions. *Note:* Numerical values used to express indentation hardness are not absolute physical quantities, but depend on the hardness scale used to express hardness. See also Brinell hardness test , Knoop (microindentation) hardness number , microindentation hardness number , nanohardness test , Rockwell hardness number , and Vickers (microindentation) hardness number .
- **indenter**
  - In hardness testing, a solid body of prescribed geometry, usually chosen for its high hardness, that is used to determine the resistance of a solid surface to penetration.
- **initial pitting**
  - Surface fatigue occurring during the early stages of gear operation, associated with the removal of highly stressed local areas and running-in (Ref 1).
- **instantaneous erosion rate**
  - The slope of a tangent to the cumulative erosion-time curve at a specified point on that curve (Ref 2).
- **interval erosion rate**
  - The slope of a line connecting two specified points on the cumulative erosion-time curve (Ref 2).
- **IRG transition diagram**
  - Developed by the International Research Group (IRG) on Wear of Engineering Materials of the Organization of Economic Cooperation and Development (OECD), it is a plot of normal force in newtons (ordinate) versus sliding velocity in meters per second (abscissa) wherein boundaries identify three distinct regions of varying lubricant effectiveness.
- **J**
- **jewel bearing**
  - A bearing made of diamond, sapphire, or a hard substitute metal (Ref 1).
- **journal**
  - The part of a shaft or axle that rotates or oscillates relative to a radial bearing. *Note:* A journal is part of a larger unit, for example, a crankshaft or lineshaft, and it is preferred that the term shaft be kept for the whole unit (Ref 1).
- **journal bearing**
  - A sliding-type bearing in which a journal rotates or oscillates relative to its housing. *Note:* A full journal bearing extends 360°, but partial bearings may extend, for example, over 180° or 120° (Ref 1).
- **judder**
  - Intermittent motion. See also spragging .
- **K**
- **kinematic viscosity**
  - See viscosity .
- **kinetic coefficient of friction**
  - The coefficient of friction under conditions of macroscopic relative motion between two bodies (Ref 2).
- **kinetic friction**
  - Friction under conditions of macroscopic relative motion between two bodies. *Note:* This term is sometimes used as a synonym for kinetic coefficient of friction ; however, it can also be used merely to indicate that the type of friction being indicated is associated with macroscopic motion rather than static conditions.
- **kinematic wear marks**
  - In ball bearings, a series of short curved marks on the surface of a bearing race due to the kinematic action of imbedded particles or asperities rolling and spinning at the ball or roller

contact points. *Note:* The length and curvature of these marks depend on the degree of spinning and on the distance from the spinning axis of the rolling element (Ref 3m).

- **Kingsbury bearing**
  - See tilting-pad bearing .
- **knock**
  - In a spark ignition engine, uneven burning of the air/fuel charge that causes violent, explosive combustion and an audible metallic hammering noise. *Note:* Knock results from premature ignition of the last part of the charge to burn (Ref 8).
- **Knoop (microindentation) hardness number**
  - Developed by F.C. Knoop in the late 1930s, it is the numerical value of microindentation hardness obtained using the Knoop indenter (diamond) and calculated as follows:

$$HK_P = 139.6 \frac{P}{d^2}$$

  - where HK_P (units of GPa) is the ASTM symbol used to represent Knoop microindentation hardness number (with the subscript indicating applied indenter load), *P* is the applied load (in grams), and *d* is the length of the long diagonal of the impression (in micrometers). *Note:* To obtain HK in kg/mm^2, replace 139.6 by 14229.0. See ASTM Standard Test Method E 384 for further details.
- **L**
- **L_{10}-life**
  - See rating life .
- **lacquer**
  - In lubrication, a deposit resulting from the oxidation and/or polymerization of fuels and lubricants when exposed to high temperatures. *Note:* Softer deposits are described as varnishes or gums (Ref 1).
- **lapping**
  - (1) A surface finishing process involving motion against an abrasive embedded in a soft metal (Ref 1). (2) Rubbing two surfaces together, with or without abrasives, for the purpose of obtaining extreme dimensional accuracy or superior surface finish (Ref 11).
- **large-end bearing**
  - See big-end bearing .
- **layer bearing**
  - A bearing constructed in layers (Ref 1). See also bimetal bearing and trimetal bearing .
- **layer-lattice material**
  - Any material having a layerlike crystal structure, but particularly solid lubricants of this type (Ref 1).
- ***L/D* ratio**
  - In bearing technology, the ratio of the axial length of a plain bearing to its diameter (Ref 1m).
- **leaded bronzes**
  - See bearing bronzes .
- **lemon bearing (elliptical bearing)**
  - A two-lobed bearing (Ref 1m).
- **light fraction**
  - The first liquid produced during the distillation of a crude oil (Ref 1).
- **limiting static friction**
  - The resistance to the force tangential to the interface that is just sufficient to initiate relative motion between two bodies under load. *Note:* The term static friction, which properly describes a tangential resistance called into operation by a force less than this, should not be substituted for limiting static friction (Ref 1).
- **linishing**
  - A method of finishing by grinding on a continuous abrasive belt (Ref 1).
- **liquid impact erosion**
  - See erosion (erosive wear) .
- **liquid impingement erosion**

- See erosion (erosive wear) .

- **little-end bearing**
  - A bearing at the smaller (piston) end of a connecting rod in an engine (Ref 1). See also big-end bearing .
- **load**
  - In tribology, the force applied normal to the surface of one body by another contacting body or bodies. *Note:* The term normal force is more precise and therefore preferred; however, the term normal load is also in use. If applied vertically, the load can be expressed in mass units, but it is preferable to use force units such as newtons (N).
- **load-carrying capacity (of a lubricant)**
  - (1) The maximum load that a sliding or rolling system can support without failure (Ref 1m). (2) The maximum load or pressure that can be sustained by a lubricant (when used in a given system under specific conditions) without failure of moving bearings or sliding contact surfaces as evidenced by seizure or welding (Ref 11).
- **loading**
  - (1) The filling of an abrasive paper or other bound abrasive material by abraded material from a second body. (2) The concentration of abrasive bound in a matrix material or added to a lap wheel as a loose abrasive.
- **lobed bearing**
  - A journal bearing with two or more lobes around its periphery produced by machining or by elastic distortion to increase stability or to provide adjustable clearance (Ref 1).
- **low-stress abrasion**
  - A form of abrasion in which relatively low contact pressures on the abrading particles or protuberances cause only fine scratches and microscopic cutting chips to be produced (Ref 3m). See also high-stress abrasion .
- **lubricant**
  - Any substance interposed between two surfaces in relative motion for the purpose of reducing the friction or wear between them (Ref 1). *Note:* The above definition implies intentional addition of a substance to an interface; however, species such as oxides and tarnishes on certain metals can also act as lubricants even though they were not added to the system intentionally.
- **lubricant compatibility**
  - See compatibility (lubricant) .
- **lubrication**
  - The reduction of frictional resistance and wear, or other forms of surface deterioration, between two load-bearing surfaces by the application of a lubricant (Ref 1).
- **lubrication regimes**
  - Ranges of operating conditions for lubricated tribosystems that can be distinguished by their frictional characteristics and/or by the manner and amount of separation of the bearing surfaces. See also boundary lubrication , elastohydrodynamic lubrication , full-film lubrication , hydrodynamic lubrication , and quasi-hydrodynamic lubrication .
- **lubricious (lubricous)**
  - Relating to a substance or surface condition that tends to produce relatively low friction.
- **lubricity**
  - The ability of a lubricant to reduce wear and friction, other than by its purely viscous properties (Ref 1).
- **M**
- **macrohardness test**
  - A term applied to such hardness testing procedures as the Rockwell, Brinell, or macro-Vickers (high-load) hardness tests to distinguish them from microindentation hardness tests such as the Knoop or Vickers tests. See also microindentation hardness number .
- **macroslip**
  - A type of sliding in which all points on one side of the interface are moving relatively to those on the other side in a direction parallel to the interface. *Note:* The term macroslip is sometimes used to denote macroslip velocity. This usage is not recommended (Ref 1). See also microslip .
- **magnetic bearing**
  - A type of bearing in which the force that separates the relatively moving surfaces is produced by a magnetic field.
- **magnetic seal**

- A seal that uses magnetic material, instead of springs or bellows, to provide the closing force (Ref 4).
- **magnetohydrodynamic lubrication**
  - Hydrodynamic lubrication in which a significant force contribution arises from electromagnetic interaction. *Note:* Magnetohydrodynamic bearings have been proposed for very high-temperature operation, for example, in liquid sodium (Ref 1).
- **magnetostrictive cavitation test device**
  - A vibratory cavitation test device driven by a magnetostrictive transducer (Ref 2).
- **main bearing**
  - A bearing supporting the main power-transmitting shaft (Ref 1).
- **mass concentration (in a slurry)**
  - The mass of solid particles per unit mass of mixture, expressed in percent (Ref 13).
- **maximum erosion rate**
  - The maximum instantaneous erosion rate in a test that exhibits such a maximum followed by decreasing erosion rates. *Note:* Occurrence of such a maximum is typical of many cavitation and liquid impingement tests. In some instances it occurs as an instantaneous maximum; in others it occurs as a steady-state maximum that persists for some time (Ref 2).
- **maximum rate period**
  - In cavitation and liquid impingement erosion, a stage following the acceleration period, during which the erosion rate remains constant (or nearly so) at its maximum value (Ref 2).
- **mechanical activation**
  - The acceleration or initiation of a chemical reaction by mechanical exposure of a nascent solid surface. *Note:* Metal cutting is an effective method of exposing large areas of fresh surface.
- **mechanical seal**
  - See face seal .
- **mechanical stability (of a grease)**
  - Grease shear stability tested in a standard rolling tester (Ref 1).
- **mechanical wear**
  - Removal of material due to mechanical processes under conditions of sliding, rolling, or repeated impact. *Note:* The term mechanical wear includes adhesive wear , abrasive wear , and fatigue wear (Ref 1). Compare with corrosive wear and thermal wear .
- **melt lubrication**
  - Lubrication provided by steady melting of a lubricating species. Also known as phase-change lubrication (Ref 1m).
- **metallic wear**
  - Typically, wear due to rubbing or sliding contact between metallic materials that exhibits the characteristics of severe wear, for example, significant plastic deformation, material transfer, and indications that cold welding of asperities possibly has taken place as part of the wear process. See also adhesive wear and severe wear .
- **metallurgical burn**
  - Modification of the microstructure near the contact surface due to frictional temperature rise (Ref 1m).
- **metallurgical compatibility**
  - See compatibility (metallurgical) .
- **microhardness number**
  - A commonly used term for the more technically correct term microindentation hardness number .
- **microindentation**
  - (1) In hardness testing, the small residual impression left in a solid surface when an indenter, typically a pyramidal diamond stylus, is withdrawn after penetrating the surface. *Notes:* Typically, the dimensions of the microindentations are measured to determine microindentation hardness number, but newer methods measure the displacement of the indenter during the indentation process to use in the hardness calculation. The precise size required to qualify as a "microindentation" has not been clearly defined; however, typical measurements of the diagonals of such impressions range from approximately 10 to 200 μm, depending on normal force and material. (2) The process of indenting a solid surface, using a hard stylus of prescribed geometry and under a slowly applied normal force, usually for the purpose of determining its microindentation hardness number. See also Knoop (microindentation) hardness number , microindentation hardness number , and Vickers (microindentation) hardness number .

- **microindentation hardness number**
  - A numerical quantity, usually stated in units of pressure, that expresses the resistance to penetration of a solid surface by a hard indenter of prescribed geometry and under a specified, slowly applied normal force. *Notes:* The prefix "micro" indicates that the indentations produced are typically between 10.0 and 200 μm across. See also Knoop (microindentation) hardness number , nanohardness test , and Vickers (microindentation) hardness number .
- **microslip**
  - Small relative tangential displacement in a contacting area at an interface, when the remainder of the interface in the contacting area is not relatively displaced tangentially. *Notes:* Microslip can occur in both rolling and stationary contacts. (2) The term microslip is sometimes used to denote the microslip velocity. This usage is not recommended (Ref 1). See also macroslip and slip .
- **mild wear**
  - A form of wear characterized by the removal of material in very small fragments. *Notes:* Mild wear is an imprecise term, frequently used in research, and contrasted with severe wear . In fact, the phenomena studied usually involve the transition from mild to severe wear and the factors that influence this transition. Mild wear may be appreciably greater than can be tolerated in practice. With metallic sliders, mild wear debris usually consists of oxide particles (Ref 1m). See also normal wear and severe wear .
- **Miller number**
  - A measure of slurry abrasivity as related to the instantaneous mass-loss rate of a standard metal wear block at a specific time on the cumulative abrasion-corrosion time curve (Ref 13). See also slurry abrasion response number .
- **mineral oil**
  - A refined hydrocarbon oil without animal or vegetable additives (Ref 1m).
- **mist lubrication**
  - Lubrication by an oil mist produced by injecting oil into a gas stream (Ref 1).
- **Mitchell bearing**
  - See tilting-pad bearing .
- **mixed lubrication**
  - See quasi-hydrodynamic lubrication .
- **Mohs hardness**
  - The hardness of a body according to a scale proposed by Mohs, based on ten minerals, each of which would scratch the one below it (Ref 1). These minerals, in decreasing order of hardness, are:

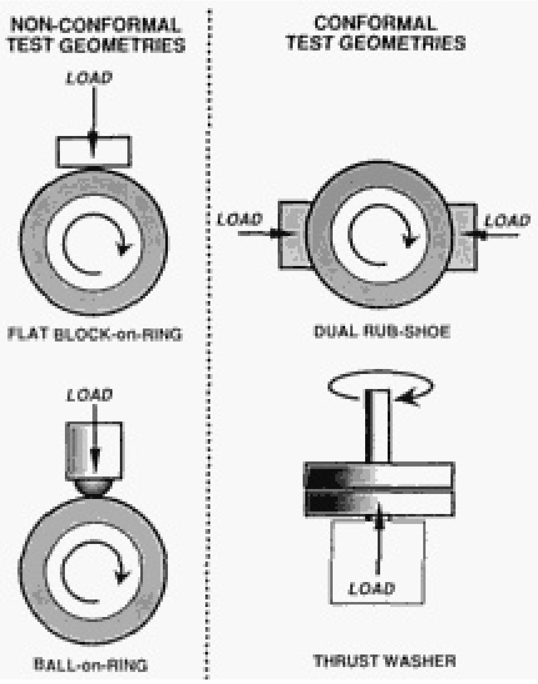
Diamond	10
Corundum	9
Topaz	8
Quartz	7
Orthoclase (feldspar)	6
Apatite	5
Fluorite	4
Calcite	3
Gypsum	2
Talc	1

- **molecular seal**
  - A seal that is basically of the windback type, but that is used for sealing vapors or gases. *Note:* Because of this use, the grooves and lands are dimensioned differently from those of a windback seal (Ref 4).
- **multigrade oil**
  - An oil having relatively little change in viscosity over a specified temperature range (Ref 1).
- **N**

- **nanohardness test**
  - An indentation hardness testing procedure, usually relying on indentation force versus tip displacement data, to make assessments of the resistance of surfaces to penetrations of the order of 10 to 1000 nm deep. *Notes:* The prefix "nano-" normally would imply hardnesses one thousand times smaller than "microhardness"; however, use of this prefix was primarily designed as a means to distinguish this technique from the more traditional microindentation hardness procedures. Most nanohardness testing procedures use three-sided pyramidal diamond indenters first described by Berkovich.
- **nascent surface**
  - A completely uncontaminated surface, produced for example by cleavage fracture under ideal vacuum conditions (Ref 1).
- **Navier-Strokes equations**
  - Basic equations of hydrodynamic lubrication (Ref 1).
- **neat oil**
  - Hydrocarbon oil with or without additives, used undiluted. *Note:* This term is used particularly in metal cutting to distinguish these fluids from soluble oils (emulsions) (Ref 1m).
- **needle bearing**
  - A bearing in which the relatively moving parts are separated by long, thin rollers that have a length-to-diameter ratio exceeding 5.0 (Ref 1m).
- **net positive suction head**
  - The difference between total pressure and vapor pressure in a fluid flow, expressed in terms of equivalent height of fluid, or "head," by the following equation:

$$\text{NPSH} = \left(\frac{P_0}{w}\right) + \left(\frac{V^2}{2g}\right) - \left(\frac{P_v}{w}\right)$$

  - where P_o is the static pressure, P_v is the vapor pressure, V is the flow velocity, w is the specific weight of fluid, and g is the gravitational acceleration. *Note:* This quantity is used in pump design as a measure of the tendency for cavitation to occur at the pump inlet. It can be related to the cavitation number (Ref 2).
- **neutral oil**
  - A lubricating oil obtained by distillation, not treated with acid or with alkali (Ref 1).
- **Newt**
  - The former English unit of kinematic viscosity (Ref 1).
- **Newtonian fluid**
  - A fluid exhibiting Newtonian viscosity wherein the shear stress is proportional to the rate of shear (Ref 1m). Compare with dilatant , rheopectic material , and thixotropy .
- **nip**
  - In a bearing, the amount by which the outer circumference of a pair of bearing shells exceeds the inner circumference of the housing (Ref 1). Also known as crush .
- **NLGI number**
  - Abbreviation for the National Lubricating Grease Institute number, which is the numerical classification of the consistency of greases, based on the ASTM D 217 test (Ref 1).
- **nominal area (of contact)**
  - The area bounded by the periphery of the region in which macroscopic contact between two solid bodies is occurring. *Note:* This is often taken to mean the area enclosed by the boundaries of a wear scar, even though the real area of contact, in which the solids are touching instantaneously, is usually much smaller. See also area of contact and apparent area of contact .
- **nonconformal surfaces**
  - (1) Surfaces whose centers of curvature are on the opposite sides of the interface, as in rolling-element bearings or gear teeth (Ref 1). (2) In wear testing, a geometric configuration in which a "point" or "line" of contact is initially established between specimens before the test is started. *Note:* Examples of nonconformal contacts are ball-on-ring and flat block-on-ring geometries (tangent to the circumferential surface). When wear occurs, the nominal area of contact tends to increase.



Nonconformal. (left) and conformal (right) test geometries

- **noncontact bearing**
  - A bearing in which no solid contact occurs between relatively moving surfaces. *Note:* Strictly speaking, a bearing in which full-film lubrication is occurring would be considered a noncontact bearing; however, this term is more typically applied to gas bearings and magnetic bearings. See also gas lubrication and magnetic bearing .
- **non-Newtonian viscosity**
  - The apparent viscosity of a material in which the shear stress is not proportional to the rate of shear (Ref 1).
- **nonsoap grease**
  - A grease made with a thickener other than soap, such as clay or asbestos (Ref 1).
- **normal force**
  - See load .
- **normal load**
  - See load .
- **normal wear**
  - Loss of material within the design limits expected for the specific intended application. *Note:* The concept of normal wear depends on economic factors, such as the expendability of a worn part.
- **normalized erosion resistance**
  - The volume loss rate of a specified reference material divided by the volume loss rate of a test material obtained under similar testing and analysis conditions. *Notes:* "Similar testing and analysis conditions" means that the volume loss rates of the two materials are determined at the corresponding portions of the erosion rate-time pattern, for example, the maximum erosion rate or the terminal erosion rate. A recommended complete wording has the form: "the normalized erosion resistance of (test material) relative to the (reference material) based on (criterion of data analysis) is (numerical value)" (Ref 2m).
- **O**
- **Ocvirk number**
  - A dimensionless number used to evaluate the performance of journal bearings, and defined by the following equation:

$$\text{Ocvirk number} = \frac{P}{\eta U}\left(\frac{c}{r}\right)^2\left(\frac{d}{b}\right)^2$$

- where *P* is the load per unit width, η is the dynamic viscosity, *U* is the surface velocity, *c* is the radial clearance, *r* is the bearing radius, *b* is the bearing length, and *d* is the bearing diameter. *Note:* This number may be used in its inverted form and is related to the Sommerfeld number (Ref 1m).

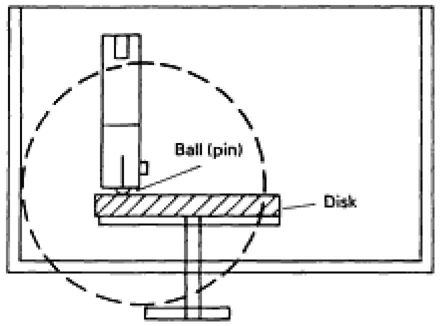
- **oil**
  - A liquid of vegetable, animal, mineral, or synthetic origin that feels slippery to the touch.
- **oil cup**
  - A device connected to a bearing that uses a wick, valve, or other means to provide a regulated flow of lubricant (Ref 1).
- **oil fog lubrication**
  - See mist lubrication .
- **oil groove**
  - A channel or channels cut in a bearing to improve oil flow through the bearing. *Note:* A similar groove may be used for grease-filled bearings (Ref 1).
- **oil pocket**
  - A depression designed to retain oil in a sliding surface (Ref 1).
- **oil ring lubrication**
  - A system of lubrication for horizontal shafts. A ring of larger diameter rotates with the shaft and collects oils from a container beneath (Ref 1).
- **oil starvation**
  - A condition in which a bearing, or other tribocomponent, receives an inadequate supply of lubricant (Ref 1m).
- **oil whirl**
  - Instability of a rotating shaft associated with instability in the lubricant film. *Note:* Oil whirl should be distinguished from shaft whirl, which depends only on the stiffness of the shaft (Ref 1).
- **oiliness**
  - See lubricity .
- **overbasing**
  - A technique for increasing the basicity of lubricants. *Note:* Overbased lubricants are used to assist in neutralizing acidic oxidation products (Ref 1).
- **oxidative wear**
  - A corrosive wear process in which chemical reaction with oxygen or oxidizing environment predominates. *Note:* Usually, oxidative wear is a form of mild wear , but it can sometimes be serious, for example, in liquid oxygen or liquid fluorine (Ref 1).
- **P**
- **pad lubrication**
  - A system of lubrication in which the lubricant is delivered to a bearing surface by a pad of felt or similar material (Ref 1).
- **partial (journal) bearing**
  - A bearing in which the bore extends not more than half the circumference of the journal (Ref 1).
- **partial hydrodynamic lubrication**
  - See quasi-hydrodynamic lubrication .
- **pedestal bearing**
  - A bearing that is supported on a column or pedestal rather than on the main body of the machine (Ref 1).
- **peening wear**
  - Removal of material from a solid surface caused by repeated impacts on very small areas (Ref 1m).
- **penetration (of a grease)**
  - The depth in $\frac{1}{10}$ mm that a standard cone penetrates the sample in a standard cup under prescribed conditions of weight, time (5 s), and temperature (25 °C, or 77 °F). *Notes:* The result depends on whether or not the grease has been subjected to shear. In unworked penetration, the

grease is transferred with as little deformation as possible or is tested in its container. In worked penetration, the grease is subjected to 60 double strokes in a standard device. In prolonged worked penetration, the grease is worked for a specified period before the 60 strokes. The results may be quoted as penetration number or penetration value (Ref 1m).

- **penetration hardness number**
  - Any numerical value expressing the resistance of a body to the penetration of a second, usually harder, body.
- **penetrometer**
  - In grease technology, an instrument for measuring the consistency of a grease by allowing a cone to penetrate into the grease under controlled conditions (Ref 1). See also penetration (of a grease) .
- **petroleum oil**
  - See mineral oil .
- **Petroff equation**
  - An equation describing the viscous power loss in a concentric bearing full of lubricant. The resisting torque on the shaft (T_o = shear stress × shaft radius × bearing area) is given by:

$$T_0 = \frac{\pi^2 \eta NLD^2}{2c}$$

  - where π = 3.1416, η is the dynamic viscosity, N is the shaft speed, L is the bearing length, D is the shaft diameter, and $2c$ is the diametral clearance (Ref 1m).
- **phase-change lubrication**
  - See melt lubrication .
- **phosphor bronzes**
  - See bearing bronzes .
- **pin-on-disk machine**
  - A tribometer in which one or more relatively moving styli (that is, the "pin" specimen) is loaded against a flat disk specimen surface such that the direction of loading is parallel to the axis of rotation of either the disk or the pin-holding shaft, and a circular wear path is described by the pin motion. *Notes:* The typical pin-on-disk arrangement resembles that of a traditional phonograph. Either the disk rotates or the pin specimen holder rotates so as to produce a circular path on the disk surface. An arrangement wherein the pin specimen is loaded against the curved circumferential surface of a flat disk is not generally considered to be a pin-on-disk machine.



Pin-on-disk machine test configuration

- **piston-pin bearing**
  - See little-end bearing .
- **pivot bearing**
  - An axial-load, radial-load type bearing that supports the end of a rotating shaft or pivot (Ref 1).
- **pivoted-pad bearing**
  - See tilting-pad bearing .

- **plain bearing**
  - Any simple sliding-type bearing, as distinct from pad- or rolling-type bearings (Ref 1).
- **plain journal bearing**
  - A plain bearing in which the relatively sliding surfaces are cylindrical and in which there is relative angular motion. *Note:* One surface is usually stationary and the force acts perpendicularly to the axis of rotation (Ref 1).
- **plain thrust bearing**
  - A plain bearing of the axial-load type, with or without grooves (Ref 1).
- **plastohydrodynamic lubrication**
  - A condition of lubrication in which the friction and film thickness between two bodies in relative motion are determined by plastic deformation of the bodies in combination with the viscous properties of the lubricant at the prevailing pressure, temperature, and rate of shear (Ref 1). Compare with elastohydrodynamic lubrication .
- **plowing (ploughing)**
  - The formation of grooves by plastic deformation of the softer of two surfaces in relative motion. *Notes:* The contribution of plowing to frictional resistance is to be distinguished from the contribution of shearing, especially in the classical hemisphere-on-flat model system. In plowing, local solid-phase welding is ignored (Ref 1m).
- **pocket**
  - In a rolling-element bearing, the portion of the case that is shaped to receive the rolling element (Ref 1). Compare with oil pocket .
- **pocket-thrust bearing**
  - An externally pressurized thrust bearing having three or more hydrostatic pads with central relieved chambers of pockets supplied with pressurized oil (Ref 1).
- **poise**
  - (P). The centimeter-gram-second (cgs) unit of dynamic viscosity (Ref 1).
- **Poisseuille**
  - (P1). The meter-kilogram-second (mks) or Système International d'Unités (SI) unit of dynamic viscosity. *Note:* 1 Pl = 10 P (Ref 1).
- **polishing**
  - A surface-finishing process utilizing successive grades of abrasive (Ref 1).
- **polishing wear**
  - An extremely mild form of wear for which the mechanism has not been clearly identified, but that may involve extremely fine-scale abrasion, plastic smearing of micro-asperities, and/or tribochemical material removal.
- **porous bearing**
  - A bearing made from porous material such as compressed and sintered metal powder. *Note:* The pores may act as reservoirs or passages for supplying fluid lubricant, or the bearing may be impregnated with solid lubricant (Ref 1).
- **positive-contact bushing**
  - A bushing, the inside diameter of which has direct contact with the outside diameter of a shaft or sleeve. *Note:* Radial or axial clearances are provided in the housing (Ref 4m).
- **positive-contact seal**
  - A seal, the primary function of which is achieved by one surface mating with another. *Note:* Examples include lip, circumferential, and face-type seals (Ref 4m). See also face seal .
- **pour point**
  - The lowest temperature at which a lubricant can be observed to flow under specified conditions (Ref 1).
- **pour-point depressant**
  - An additive that lowers the pour point of a lubricant (Ref 1m).
- **pressure-viscosity coefficient**
  - The slope of a graph showing variation in the logarithm of viscosity with pressure. *Note:* The use of the term pressure-viscosity coefficient assumes a linear relationship (Barus equation) (Ref 1).
- **pressure lubrication**
  - A system of lubrication in which the lubricant is supplied to the bearing under pressure (Ref 1).
- **pressurized gas lubrication**
  - A system of lubrication in which a gaseous lubricant is supplied under sufficient external pressure to separate the opposing surfaces by a gas film (Ref 1).

- **primary leakage**
  - In seals, the leakage of a mechanical seal, with the fluid escaping from the region between the end faces of the primary sealing elements (Ref 4).
- **protuberances**
  - See asperities .
- **prow formation**
  - See wedge formation .
- **pseudoplastic behavior**
  - A decrease in viscosity with increasing shear stress (Ref 1). Compare with dilatant , rheopectic material , and thixotropy .
- **pumping efficiency**
  - In a bearing, the ratio of actual oil flow to the maximum theoretical flow for a bearing with a 180° oil film operating at an eccentricity ratio of unity (Ref 1).
- **pusher-type seal**
  - A mechanical seal in which the secondary seal is pushed along the shaft or sleeve to compensate for face wear (Ref 4).
- ***PV* factor**
  - The product of bearing pressure and surface velocity traditionally expressed in terms of (lb/in.^{2}) × (ft/min); the ISO equivalent is Pa · m/s (Ref 1m).
- **Q**
- **quasi-hydrodynamic lubrication**
  - A loosely defined regime of lubrication, especially in metalworking, where thin-film lubrication predominates (Ref 1).
- **quench**
  - A neutral fluid that is introduced into a seal chamber or cavity for the purpose of diluting fluid that may have leaked through a seal (Ref 4).
- **quenching oil**
  - Oil used for quenching metals during a heat-treating operation.
- **R**
- **race (or raceway)**
  - The groove or path in which the rolling elements in a rolling-contact bearing operate (Ref 1m).
- **radial lip seal**
  - A radial type of seal that features a flexible sealing member, referred to as a lip. *Note:* The lip is usually of an elastomeric material. It exerts radial sealing pressure on a mating shaft in order to retain fluids and/or exclude foreign matter (Ref 4m).
- **radial-load bearing**
  - A bearing in which the load acts in a radial direction with respect to the axis of rotation (Ref 1).
- **rain erosion**
  - A form of liquid impingement erosion in which the impinging liquid particles are raindrops. *Note:* This form of erosion is of particular concern to designers and material selectors for external surfaces of rotary-wing and fixed-wing aircraft. See also erosion (erosive wear) .
- **rating life**
  - Currently the fatigue life in millions of revolutions or hours at a given operating speed that 90% of a group of substantially identical rolling-element bearings will survive under a given load. *Note:* The 90% rating life is frequently referred to as L_{10}-life or B_{10}-life (Ref 1). From Ref 6, the rating life in revolutions can be obtained from:

$$L_{10} = \left(\frac{C}{P}\right)^K \times 10^6$$

  - where C is the basic load rating (in pounds), P is the equivalent radial load (in pounds), and K is a constant (3 for ball bearings and 10/3 for roller bearings). For a rating life in hours, use:

$$L_{10} = \frac{16700}{N}\left(\frac{C}{P}\right)^K$$

- where *N* is the rotational speed in rev/min.

- **Rayleigh step bearing**
  - A stepped-pad bearing having one step only in each pad (Ref 1).
- **real area of contact**
  - In tribology, the sum of the local areas of contact between two solid surfaces, formed by contacting asperities, that transmit the interfacial force between the two surfaces (Ref 2). Contrast with apparent area of contact .
- **red mud**
  - See cocoa .
- **Redwood viscosity**
  - A commercial measure of viscosity expressed as the time in seconds required for 50 cm^3 of a fluid to flow through a tube of 10 mm length and 1.5 mm diameter at a given temperature. *Note:* It is recommended that fundamental viscosity units should be used (Ref 1).
- **Rehbinder effect**
  - Modification of the mechanical properties at or near the surface of a solid, attributable to interaction with a surfactant (Ref 1).
- **repeated impact**
  - See impingement .
- **restrictor rings**
  - Rings, usually faced with white metal , placed outside a bearing to prevent fluid from being discharged (Ref 1).
- **retainer**
  - See cage .
- **Reyn**
  - The former English unit of dynamic viscosity (Ref 1).
- **Reynold's equation**
  - A basic equation of hydrodynamic lubrication (Ref 1).
- **rheodynamic lubrication**
  - A regime of lubrication in which the rheological (non-Newtonian) properties of the lubricant predominate. *Note:* This term is especially applied to lubrication with grease (Ref 1).
- **rheology**
  - The study of the deformation and/or flow of matter, in terms of stress, strain, temperature, and time (Ref 1).
- **rheopectic material**
  - A material that shows an increase in viscosity with time under a constant shear stress. After removal of the shear stress, the viscosity slowly returns to its original level (Ref 1). Compare with thixotropy .
- **ridging (wear)**
  - A deep form of scratching in parallel ridges usually caused by plastic flow of the subsurface layer (Ref 1).
- **ring seal**
  - A piston ring-type seal that assumes its sealing position under the pressure of the fluid to be sealed (Ref 4).
- **ripple formation (rippling)**
  - Formation of periodic ridges and valleys transverse to the direction of motion (Ref 1).
- **Rockwell hardness number**
  - A number derived from the net increase in the depth of impression as the load on a penetrator is increased from a fixed minor load to a major load and then returned to the minor load (Ref 11). *Note:* Various scales of Rockwell hardness numbers have been developed based on the hardness of the materials to be evaluated. The scales are designated by alphabetic suffixes to the hardness designation, for example, HRB, HRC. A detailed description of the Rockwell hardness testing procedure can be found in ASTM Standard E 40.

- **Rockwell superficial hardness test**
  - The same test as used to determine the Rockwell hardness number except that smaller minor and major loads are used (Ref 11m).
- **roller bearing**
  - A bearing in which the relatively moving parts are separated by rollers (Ref 1).
- **rolling**
  - (pure rolling with no sliding and no spin). A motion of two relatively moving bodies, of opposite curvature, whose surface velocities in the common contact area are identical with regard to both magnitude and direction (Ref 1m). See also sliding and spin .
- **rolling-contact fatigue**
  - Repeated stressing of a solid surface due to rolling contact between it and another solid surface or surfaces. *Note:* Continued rolling-contact fatigue of bearing surfaces may result in rolling-contact damage in the form of subsurface fatigue cracks and/or material pitting and spallation.
- **rolling-contact wear**
  - Wear to a solid surface that results from rolling contact between that surface and another solid surface or surfaces.
- **rolling-element bearing**
  - A bearing in which the relatively moving parts are separated by balls, rollers, or needles (Ref 1).
- **rolling velocity**
  - See sweep velocity .
- **rotary seal**
  - A mechanical seal that rotates with a shaft and is used with a stationary mating ring (Ref 4).
- **rubbing bearing**
  - A bearing in which the relatively moving parts slide without deliberate lubrication (Ref 1).
- **rugosities**
  - See asperities .
- **run-in**
  - (noun). (1) In tribology, an initial transition process occurring in newly established wearing contacts, often accompanied by transients in coefficient of friction, wear rate, or both, that are uncharacteristic of the given tribological system's long-term behavior (Ref 2). (2) In seals, the period of initial operation during which the seal-lip wear rate is greatest and the contact surface is developed (Ref 4m).
- **run in**
  - (verb). In tribology, to apply a specified set of initial operating conditions to a tribological system in order to improve its long-term frictional or wear behavior, or both (Ref 2). *Note:* The run-in may involve conditions either more severe or less severe than the normal operating conditions of the tribosystem, and may also involve the use of special lubricants and/or surface chemical treatments. See also break-in .
- **running-in**
  - The process by which machine parts improve in conformity, surface topography, and frictional compatibility during the initial stage of use. *Note:* Chemical processes, including formation of an oxide skin, and metallurgical processes, such as strain hardening, may contribute (Ref 1).
- **S**
- **saponify**
  - (1) To convert into soap. (2) To subject to, or to undergo, saponification (Ref 5).
- **saponification number**
  - A measure of the amount of constituents of petroleum that will easily saponify under test conditions, determined by the number of milligrams of sodium hydroxide that is consumed by 1 g of oil under test conditions. *Note:* Saponification number is a measure of fatty materials compounded in an oil (Ref 5m).
- **sauter mean diameter**
  - The diameter of a drop that has the same ratio of volume-to-surface area as the ratio of total volume-to-total surface area in a distribution of drops, as computed from the equation:

$$\text{SMD} = \Sigma_i n_i d_i^3 / \Sigma_i n_i d_i^2$$

- where *i* is a sampling size interval, d_i is the drop diameter, and n_i is the number of drops in that interval (Ref 2).
- **Saybolt Universal Viscosity**
  - A commercial measure of viscosity expressed as the time in seconds required for 60 cm^3 of a fluid to flow through the orifice of the Standard Saybolt Universal Viscometer at a given temperature under specified conditions (Ref 1).
- **scabbing**
  - (1) In wear, a loosely used term referring to the formation of bulges in the surface (Ref 1). (2) In fracture mechanics, it is identical with spalling (Ref 1).
- **scaling**
  - The formation of a thick oxide on the surface of a heated metal. *Note:* Scaling is to be distinguished from rusting, which involves the formation of hydrated oxides (Ref 1).
- **scoring**
  - (1) The formation of severe scratches in the direction of sliding. *Notes:* Scoring may be due to local solid-phase welding or to abrasion. In the United States, the term scuffing is sometimes used as a synonym for scoring. Minor damage should be called scratching rather than scoring (Ref 1). (2) In tribology, a severe form of wear characterized by the formation of extensive grooves and scratches in the direction of sliding (Ref 2). (3) The act of producing a scratch or narrow groove in a surface by causing a sharp instrument to move along that surface. See also galling .
- **scouring abrasion**
  - Same as abrasion .
- **scraper**
  - An exclusion seal that has metallic or other firm lips or scraping elements. It serves to remove foreign material from a reciprocating shaft (Ref 4).
- **scratch**
  - A groove produced in a solid surface by the cutting and/or plowing action of a sharp particle or protuberance moving along that surface.
- **scratch hardness test**
  - A form of hardness test in which a sharp-pointed stylus or corner of a mineral specimen is traversed along a surface so as to determine the resistance of that surface to cutting or abrasion. *Notes:* The Mohs hardness test is among the most widely used forms of scratch hardness tests, but is mainly applied to mineralogical specimens or abrasives. Other scratch hardness tests involve using diamond cones, pyramids, and spherical tips, but such scratch hardness tests have not been established and standardized to the extent that macro- and microindentation hardness tests have been.
- **scratching**
  - The formation of fine scratches in the direction of sliding. *Notes:* Scratching may be due to asperities on the harder slider or to hard particles between the surface or embedded in one of them. Scratching is to be considered less damaging than scoring (Ref 1). See also abrasion , plowing (ploughing) , and ridging wear .
- **scratching abrasion**
  - See low-stress abrasion .
- **scuffing**
  - (1) Localized damage caused by the occurrence of solid-phase welding between sliding surfaces, without local surface melting. *Notes:* In the United Kingdom, scuffing implies local solid-phase welding only. In the United States, scuffing may include abrasive effects and the term scoring is sometimes used as a synonym (Ref 1). (2) A mild degree of galling that results from the welding of asperities due to frictional heat. The welded asperities break, causing surface degradation (Ref 4). *Note:* In general, the term scuffing has been used in so many different ways that its use should be avoided whenever possible, and instead replaced with a more precise description of the specific type of surface damage being considered.
- **seal**
  - (1) In tribology, a device designed to prevent leakage between relatively moving parts (Ref 1). (2) A device designed to prevent the movement of fluid from one chamber to another, or to exclude contaminants (Ref 4).
- **sealing face**

- The lapped surface of a seal that comes in close proximity to the face of the mating ring of a face seal, thus forming the primary seal. With reference to lip seals, the preferred term is seal contact surface (Ref 4).

- **seal nose**
  - The part of the primary seal ring of a face seal that comes in closest proximity to the mating surface and that, together with the mating surface, forms the primary seal (Ref 4).
- **secondary seal**
  - A device, such as bellows, piston ring, or O-ring, that allows axial movement of the primary seal of a mechanical face seal without undue leakage (Ref 4).
- **seizure**
  - The stopping of relative motion as the result of interfacial friction. *Notes:* Seizure may be accompanied by gross surface welding. The term is sometimes used to denote scuffing (Ref 1m).
- **selective transfer**
  - A process involving the transfer and attachment of a specific species from one surface to the mating surface during sliding. *Notes:* This term is to be distinguished from the general tribological term transfer , which involves the same general process, but which, when used by itself, does not discriminate as to which of the species present in a multiconstituent surface is transferred during sliding. This term is more commonly used in the Russian literature of tribology.
- **self-acting bearing**
  - See gas bearing and self-lubricating bearing .
- **self-aligning bearing**
  - A rolling-element bearing with one spherical raceway that automatically provides compensation for shaft or housing deflection or misalignment (Ref 1). Compare with aligning bearing .
- **self-lubricating bearing**
  - A bearing independent of external lubrication. *Note:* These bearings may be sealed for life after packing with grease or may contain self-lubricating material (Ref 1).
- **self-lubricating material**
  - Any solid material that shows low friction without application of a lubricant. *Notes:* Examples are graphite, molybdenum disulfide, and polytetrafluoroethylene. Taken in a broader context, the term can also refer to a composite material into which a lubricious species has been incorporated (Ref 1m). See also solid lubricant .
- **separator**
  - In rolling-element bearings, the part of a cage that lies between the rolling elements. *Note:* This term is sometimes used as a synonym for cage (Ref 1m).
- **severe wear**
  - A form of wear characterized by removal of material in relatively large fragments. *Notes:* Severe wear is an imprecise term, frequently used in research, and contrasted with mild wear . In fact, the phenomena studied usually involve the transition from mild to severe wear and the factors that influence that transition. With metals, the fragments are usually predominantly metallic rather than oxidic. Severe wear is frequently associated with heavy loads and/or adhesive contact (Ref 1).
- **shaft run-out**
  - Twice the distance that the center of a shaft is displaced from the axis of rotation; that is, twice the eccentricity (Ref 4).
- **shake-down (of surface layers)**
  - The establishment of a state of stress in which no further plastic flow occurs (Ref 1m).
- **shear stability**
  - The ability of a lubricant to withstand shearing without degradation (Ref 1). See also penetration (of a grease) .
- **shear thickening**
  - An increase in viscosity with an increase in shear stress or time (Ref 1). See also shear thinning .
- **shear thinning**
  - A decrease in viscosity with an increase in shear stress or time. *Note:* The decrease in viscosity may be temporary or permanent. The latter happens when the shear stress is sufficiently large to rupture a chemical bond, so that the sheared liquid has a lower viscosity than it had prior to shearing (Ref 1). See also shear thickening .
- **shelling**

- A term used in railway engineering to describe an advanced phase of spalling (Ref 1).
- **skidding**
  - A form of nonuniform relative motion between solid surfaces due to rapid periodic changes in the traction between those surfaces.
- **sleeve bearing**
  - A cylindrical plain bearing used to provide radial location for a shaft, which moves axially. *Note:* Sleeve bearing is sometimes used to denote journal bearing (Ref 1). See also sliding bearing .
- **slide-roll ratio**
  - See slide-sweep ratio .
- **slide-sweep ratio**
  - The ratio of sliding velocity to sweep velocity, for example, in a pair of gears. *Note:* In rolling, the slide-sweep ratio is called the slide-roll ratio (Ref 1).
- **sliding**
  - (pure sliding with no rolling or spin). A motion of two relatively moving bodies, in which their surface velocities in the common contact area are different with regard to magnitude and/or direction (Ref 1). See also rolling , spin , and specific sliding .
- **sliding bearing**
  - A bearing in which predominantly sliding contact occurs between relatively moving surfaces. *Note:* Sliding bearings may be either unlubricated, liquid lubricated, grease lubricated, or solid lubricated.
- **sliding velocity**
  - The difference between the velocities of each of the two surfaces relative to the point of contact (Ref 1).
- **sludge**
  - A coagulated mass, often containing foreign matter, formed at low temperature in combustion engines from oil oxidation residues, carbon, and water (Ref 1m).
- **slumpability**
  - The flow of gravity of a grease in a container, allowing it to feed out into a pump or can. *Note:* Slumpability also influences the leakage of grease from a bearing (Ref 1).
- **slurry**
  - A mixture of solid particles in a liquid, of such consistency so as to be capable of being pumped like a liquid (Ref 13).
- **slurry abrasion response (SAR) number**
  - A measure of the relative abrasion response of any material in any slurry, as related to the instantaneous rate of mass loss of a specimen at a specific time on the cumulative abrasion-corrosion time curve, converted to volume or thickness loss rate (Ref 13). *Notes:* The SAR number is determined by a procedure described in ASTM Standard Test Method G 75. The Miller number , also described in ASTM G 75, is a measure of the abrasivity of a slurry.
- **slurry abrasivity**
  - The relative tendency of a particular moving slurry to produce abrasive and corrosive wear compared with other slurries (Ref 13).
- **slurry erosion**
  - Erosion produced by the movement of a slurry past a solid surface.
- **slushing oil**
  - A mineral oil containing additives that enable it to protect the parts of a machine against rusting (Ref 1).
- **smearing**
  - Mechanical removal of material from a surface, usually involving plastic shear deformation, and redeposition of the material as a thin layer on one or both surfaces (Ref 1m). See also transfer .
- **soap**
  - In lubrication, a compound formed by the reaction of a fatty acid with a metal or metal compound. *Note:* Metallic soaps formed by reaction *in situ* are an important group of boundary lubricants (Ref 1).
- **solid-film lubrication**
  - Lubrication by application of solid lubricants (Ref 1).
- **solid lubricant**
  - Any solid used as a powder or thin film on a surface to provide protection from damage during relative movement, and to reduce friction and wear. *Notes:* Many solid lubricants have a layer

(lamellar) structure, for example, graphite and molybdenum disulfide. Certain solid materials lubricate only in the molten state at the interface. Examples are glass and ice, which are not solid lubricants (Ref 1).

- **soluble oil**
  - A mineral oil containing additives that enable it to form a stable emulsion with water. *Note:* Soluble oils are not soluble in water (Ref 1).
- **Sommerfeld number**
  - A dimensionless number that is used to evaluate the performance of journal bearings. It is numerically defined as follows:

$$\frac{P}{\eta U}\left(\frac{c}{r}\right)^2$$

  - where *P* is the load per unit width, η is the dynamic viscosity, *U* is the surface velocity, *c* is the radial clearance, and *r* is the bearing radius. *Notes:* At lower concentricities it is convenient to use the Sommerfeld number in the form given. Because it tends to infinity as the eccentricity approaches unity, the reciprocal form is frequently used in the case of heavily loaded bearings. The expression:

$$\frac{\eta N}{p}\left(\frac{r}{c}\right)^2$$

  - in which *N* is the frequency of rotation and *p* is the pressure, is sometimes referred to as the Sommerfeld number, particularly in the United States (Ref 1m). See also Hershey number and Ocvirk number .
- **spalling**
  - (1) Separation of particles from a surface in the form of flakes. *Notes:* The term spalling is commonly associated with rolling-element bearings and with gear teeth. Spalling is usually a result of subsurface fatigue and is more extensive than pitting (Ref 1). (2) In tribology, the separation of macroscopic particles from a surface in the form of flakes or chips, usually associated with rolling-element bearings and gear teeth, but also resulting from impact events (Ref 2). See also fatigue wear , scabbing , and shelling .
- **spark erosion**
  - See electrical pitting .
- **specific sliding**
  - The ratio of the algebraic difference between the surface velocities of two bodies in relative motion to their sum (Ref 1).
- **specific wear rate**
  - In journal bearings, the proportionality constant *K* in the equation:

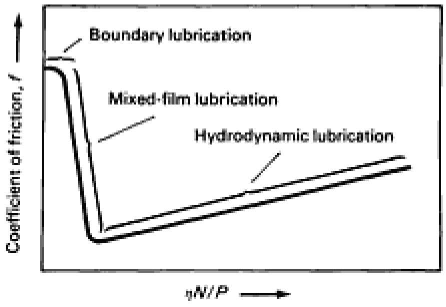
$$h = Kpvt$$

  - where *h* is the radial wear in the bearing, *p* is the apparent contact pressure, *v* is the velocity of the journal, and *t* is the sliding time (Ref 14). *Note:* The constant *K* has also been called the wear factor , but there are other definitions for the term wear factor that do not necessarily refer to journal bearings or derive their meanings from the above equation.
- **spherical bearing**
  - A bearing that is self-aligning by virtue of its partially spherical form (Ref 1).
- **spherical roller bearing**
  - (1) A spherical bearing containing rollers (Ref 1). (2) A roller bearing containing barrel-shaped or hour glass-shaped rollers riding on spherical (concave or convex) races to provide self-aligning capability (Ref 8).

- **spin**
  - In bearings, rotation of a rolling element about an axis normal to the contact surfaces (Ref 1). See also rolling and sliding .
- **spindle oil**
  - An oil of low viscosity used to lubricate high-speed light spindles (Ref 1).
- **split seal**
  - A seal that has its primary sealing elements split in a plane parallel to the axis of the shaft such that, instead of the rings being continuous, they are essentially two semicircles. Modified designs of lip seals feature units with a single lip separation and with one or more separations of the metallic stiffening mechanisms (Ref 4).
- **splash lubrication**
  - A system of lubrication in which the lubricant is splashed onto the moving parts (Ref 1).
- **sponge effect**
  - See squeeze effect .
- **spragging**
  - Intermittent motion arising from design features that allow an increase in tangential force or displacement to produce an increase in normal force (Ref 1).
- **spreader**
  - An axial groove in a plain bearing designed to spread oil along the bearing (Ref 1). See also gutterway .
- **spreader pockets**
  - Depressions in a sliding surface designed to distribute lubricant (Ref 1).
- **squeeze effect**
  - The production of lubricant from a porous retainer by application of pressure. Also known as sponge effect (Ref 1). (2) The persistence of a film of fluid between two surfaces that approach each other in the direction of their common normal (Ref 1).
- **starting torque**
  - The torque that is required for initiating rotary motion (Ref 4).
- **static coefficient of friction**
  - The coefficient of friction corresponding to the maximum friction force that must be overcome to initiate macroscopic motion between two bodies (Ref 2).
- **static equivalent load**
  - (P_o). In rolling-element bearings, the static load which, if applied, would give the same life as that which the bearing will attain under actual conditions of load and rotation (Ref 6m).
- **static friction**
  - See limiting static friction .
- **static load rating**
  - (C_o). In rolling-element bearings, the static load that corresponds to a permanent deformation of rolling element and race at the most heavily stressed contact of 0.00001 of the rolling-element diameter (Ref 6m).
- **static viscosity**
  - See viscosity .
- **stave bearing**
  - A sleeve bearing consisting of several axially held slats or staves on the outer surface of which the bearing material is bonded (Ref 1).
- **step bearing**
  - A plain surface bearing that supports the lower end of a vertical shaft. Other types of bearings may be thus described when they are mounted on a step or bracket (Ref 1). See also Rayleigh step bearing and stepped bearing .
- **stepped bearing**
  - A thrust bearing in which the working face consists of one or more shallow steps. *Notes:* Bearings of this type were originally described by Rayleigh. A distinction should be drawn between a stepped bearing and a step bearing (Ref 1).
- **stern-tube bearing**
  - The final bearing through which a propeller shaft passes in a boat or ship (Ref 1m).
- **stick-slip**
  - A relaxation oscillation usually associated with a decrease in the coefficient of friction as the relative velocity increases. *Notes:* Stick-slip was originally associated with formation and

destruction of interfacial junctions on a microscopic scale. This is often the basic cause. The period depends on the velocity and on the elastic characteristics of the system. Stick-slip will not occur if the static friction is equal to or less than the dynamic friction. The motion resulting from stick-slip is sometimes referred to as jerky motion (Ref 1). See also spragging .

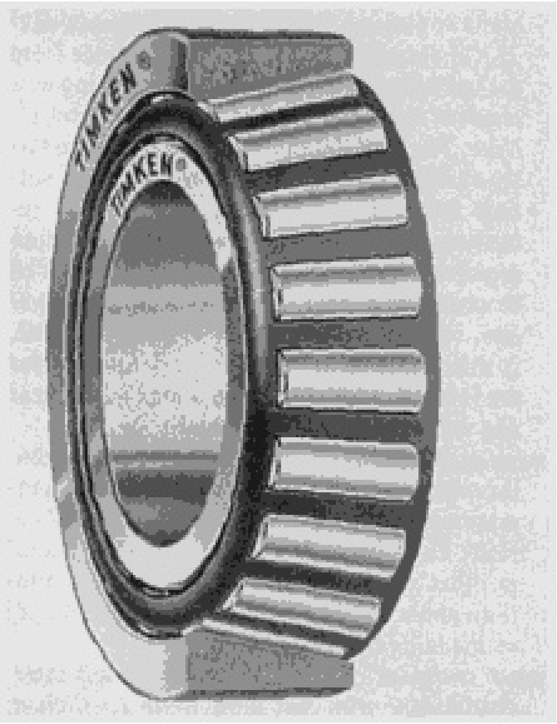
- **stiction**
  - A term sometimes used to signify the condition in which the frictional resistance is sufficient to prevent macroscopic sliding (Ref 1).
- **Stoke (centistoke)**
  - The centimeter-gram-second (cgs) unit of kinematic viscosity (Ref 1).
- **storage stability**
  - A measure of the ability of a lubricant to undergo prolonged periods of storage without showing any adverse conditions due to oxidation, oil separation, contamination, or any type of deterioration (Ref 5).
- **Stribeck curve**
  - A graph showing the relationship between coefficient of friction and the dimensionless number ($\eta N/P$), where η is the dynamic viscosity, *N* is the speed (revolutions per minute for a journal), and *P* is the load per unit of projected area. *Note:* The symbols Z and *v* (linear velocity) may be substituted for η and *N,* respectively (Ref 1).



Stribeck curve: coefficient of friction (and type of lubrication) versus dimensionless variable $\eta N/P$

- **sulfochlorinated lubricant**
  - A lubricant containing chlorine and sulfur compounds, which react with a rubbing surface at elevated temperatures to form a protective film. *Note:* There may be a synergistic effect, producing faster reaction than with sulfur or chlorine additives alone (Ref 1).
- **sulfurized lubricant**
  - A lubricant containing sulfur or a sulfur compound that reacts with a rubbing surface at elevated temperatures to form a protective film. *Note:* The shear strength of the sulfide film formed on ferrous materials is lower than that of the metal but greater than that of the film formed by reaction with a chlorinated lubricant (Ref 1).
- **superficial hardness test**
  - See Rockwell superficial hardness test .
- **surface damage**
  - In tribology, damage to a solid surface resulting from mechanical contact with another substance, surface, or surfaces moving relatively to it and involving the displacement or removal of material. *Note:* In certain contexts, wear is a form of surface damage in which material is progressively removed. In another context, surface damage involves a deterioration of function of a solid surface even though there is no material loss from that surface. Surface damage may therefore precede wear.
- **surface distress**
  - In bearings and gears, damage to the contacting surfaces that occurs through intermittent solid contact involving some degree of sliding and/or surface fatigue. *Note:* Surface distress can occur in numerous forms depending on the conditions under which the bearing or gear was operated and on the nature of the interaction between the contacting surfaces.

- **surfactant**
  - A chemical substance characterized by a strong tendency to form adsorbed interfacial films when in solution, emulsion, or suspension, thus producing effects such as low surface tension, penetration, boundary lubrication, wetting, and dispersing (Ref 1). See also Rehbinder effect .
- **sweating**
  - Exudation of bearing material or lubricant due to high temperature (Ref 1).
- **sweep velocity**
  - The mean of the surface velocities of two bodies at the area of contact. *Notes:* Occasionally the sum of the velocities is quoted instead of the mean. In rolling, the sweep velocity is also called the rolling velocity (Ref 1).
- **syneresis (of a grease)**
  - See bleeding .
- **synthetic oil**
  - Oil produced from chemical synthesis rather than from petroleum. *Note:* Examples are esters, ethers, silicons, silanes, and halogenated hydrocarbons.
- **T**
- **tandem seal**
  - A multiple-seal arrangement consisting of two seals mounted one after the other, with the faces of the seal heads oriented in the same direction (Ref 4).
- **taper section**
  - A section cut obliquely through a surface and prepared metallographically. *Note:* The angle is often chosen to increase the vertical magnification of surface features by a factor of 5 or 10 (Ref 1).
- **tapered land bearing**
  - A thrust bearing containing pads of fixed taper (Ref 1).
- **tapered roller bearing**
  - A rolling-element bearing containing tapered rollers (Ref 1).



Tapered roller bearing (cutaway view). Courtesy of D. Huffman, The Timken Company

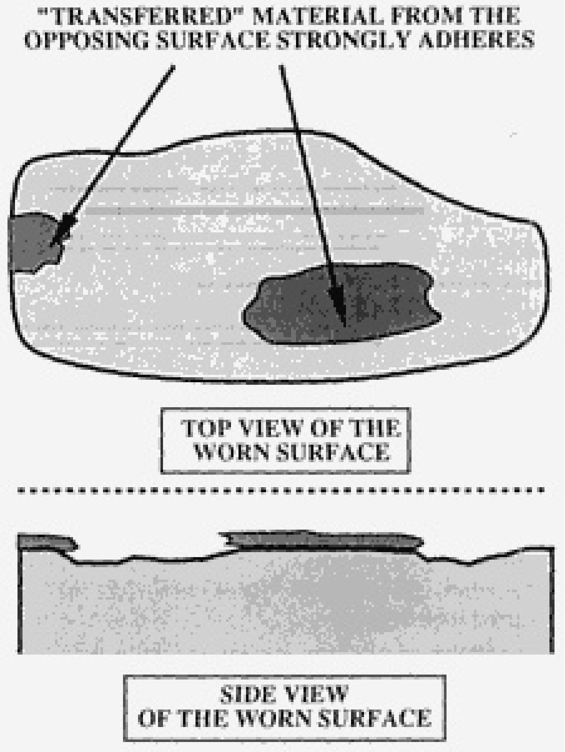
- **Taylor vortices**
  - In a journal bearing, vortices formed in a liquid occupying the annular space between two concentric cylinders (Ref 1).
- **terminal erosion rate**

- The final steady-state erosion rate that is reached (or appears to be approached asymptotically) after the erosion rate has declined from its maximum value. This occurs in some, but not all, cavitation and liquid impingement tests (Ref 2).

- **terminal period**
  - In cavitation and liquid impingement erosion, a stage following the deceleration period, during which the erosion rate has leveled off and remains approximately constant (sometimes with superimposed fluctuations) at a value substantially lower than the maximum rate attained earlier (Ref 2).
- **textile oil**
  - (1) An oil used to lubricate thread or yarn to prevent breakage during spinning and weaving. (2) An oil acceptable for direct contact with fibers during textile production (Ref 1).
- **thermal taper**
  - See thermal wedge .
- **thermal wear**
  - Removal of material due to softening, melting, or evaporation during sliding or rolling. *Notes:* Thermal shock and high-temperature erosion may be included in the general description thermal wear. Wear by diffusion of separate atoms from one body to the other, at high temperatures, is sometimes denoted as thermal wear (Ref 1).
- **thermal wedge**
  - The increase in pressure due to the expansion of the lubricant, for example, in a parallel thrust bearing. *Note:* Thermal distortion of the bearing surfaces may also form a wedge shape. This is referred to as thermal taper (Ref 1).
- **thermoelastic instability**
  - (TEI) In sliding contact, sharp variations in local surface temperatures with the passing of asperities leading to stationary or slowly moving hot spots of significant magnitude (Ref 8).
- **thickener**
  - A solid material dispersed in a liquid lubricant to produce a grease. *Note:* Silica, clays, and metallic soaps are widely used as thickeners (Ref 1).
- **thick-film lubrication**
  - A condition of lubrication in which the film thickness of the lubricant is appreciably greater than that required to cover the surface asperities when subjected to the operating load, so that the effect of the surface asperities is not noticeable (Ref 1). See also thin-film lubrication .
- **thin-film lubrication**
  - A condition of lubrication in which the film thickness of the lubricant is such that the friction and wear between the surfaces is determined by the properties of the surfaces as well as the viscosity of the lubricant. *Notes:* Under thin-film conditions, the coefficient of friction is often 10 to 100 times greater than under thick-film conditions and wear is no longer negligible. Boundary lubrication and elastohydrodynamic lubrication are better-defined terms that should be used where possible (Ref 1).
- **thixotropy**
  - The property of recovering consistency after a decrease as a result of shearing. *Note:* Thixotropic age hardening is a more prolonged process than the instantaneous increase in apparent viscosity as shear rate decreases, which is found in non-Newtonian fluids (Ref 1). See also rheopectic material .
- **thrust bearing**
  - A bearing in which the load acts in the direction of the axis of rotation (Ref 1).
- **tilting-pad bearing**
  - A pad bearing in which the pads are free to take up a position at an angle to the opposing surface according to the hydrodynamic pressure distribution over its surface (Ref 1).
- **torque**
  - As applied to sealing, a resistance to shaft rotation caused by the frictional drag of the seal. It is normally expressed in foot-pound or inch-pound units (Ref 4). *Note:* The metric equivalent is N · m (force times distance).
- **track**
  - The mark made by a seal on the surface with which it mates (Ref 4).
- **tracking pattern**
  - The path a seal ring makes when in rubbing contact with the mating ring or seal plate (Ref 4).
- **traction**

- In rolling contacts, the tangential stress transmitted across the interface. *Notes:* The traction will in general vary from point to point over the contact area. More generally, traction may denote the force per unit area of contact (Ref 1).

- **tractive force**
  - The integral of the tangential surface stress over the area of contact (Ref 1).
- **transfer**
  - In tribology, the process by which material from one sliding surface becomes attached to another surface, possibly as the result of interfacial adhesion. *Notes:* Transfer is usually associated with adhesion, but the possibility of mechanical interlocking adherence, without adhesive bonding, exists in certain occurrences. Material may also back transfer to the surface from which it came. See also selective transfer .



Transfer (schematic)

- **transmission oil**
  - (1) Oil used for transmission of hydraulic power. (2) Oil used to lubricate automobile transmission systems (Ref 1).
- **transition diagram**
  - In tribology, a plot of two or more experimental or operating variables that indicates the boundaries between various regimes of wear or surface damage. *Notes:* The IRG transition diagram is a plot of normal force (ordinate) versus sliding velocity (abscissa), and is used to identify three regions with differing lubrication effectiveness. Various plots have been called transition diagrams, and the context of usage must be established.
- **tribo-**
  - A prefix indicating a relationship to interacting surfaces in relative motion.
- **tribochemistry**
  - The part of chemistry dealing with interacting surfaces in relative motion (Ref 1). *Note:* Tribochemistry broadly encompasses such areas as lubricant chemistry, changes in reactivity of surfaces due to mechanical contact, oxidative wear, and other phenomena.
- **triboelement**
  - A solid body that is bounded by one or more tribosurfaces and that resides within a tribosystem . *Note:* This term is often associated with H. Czichos, whose systems approach to tribology

identified triboelements. For example, in a pin-on-disk tribosystem, the pin is one triboelement and the disk is another.

- **tribology**
  - The science and technology of interacting surfaces in relative motion and of the practices related thereto. *Notes:* This term was introduced in a report by a group set up by the British Department of Education and Science. It was defined in their report "Lubrication (Tribology)" in 1966. The study of wear by erosion or cavitation erosion is included in tribology (Ref 1). (2) Friction, lubrication, and wear science and technology.
- **tribometer**
  - (1) An instrument or testing rig to measure normal and frictional forces of relatively moving surfaces (Ref 1). (2) Any device constructed for or capable of measuring the friction, lubrication, and wear behavior of materials or components.
- **tribophysics**
  - That part of physics dealing with interacting surfaces in relative motion (Ref 1).
- **triboscience**
  - The scientific discipline devoted to the systematic study of interacting surfaces in relative motion. *Note:* Triboscience includes the scientific aspects of tribochemistry , tribophysics , contact mechanics, and materials and surface sciences as related to tribology .
- **tribosurface**
  - Any solid surface whose intermittent, repeated, or continuous contact with another surface or surfaces, in relative motion, results in friction, wear, and/or surface damage. *Note:* The surface of a body subjected to a catastrophic collision would not generally be considered a tribosurface because significant damage to the entire body is involved.
- **tribosystem**
  - Any functional combination of triboelements, including thermal and chemical surroundings.
- **tribotechnology**
  - The aspect of tribology that involves engineering application of triboscience and the design, development, analysis, and repair of components for tribological applications.
- **trimetal bearing**
  - A bearing consisting of three layers. *Note:* Trimetal bearings are usually made of bronze with a white metal facing and a steel backing (Ref 1).
- **trunnion bearing**
  - A bearing used as a pivot to swivel or turn an assembly (Ref 1).
- **turbine oil**
  - An oil used to lubricate bearings in a steam or gas turbine (Ref 1).
- **U**
- **unctuous**
  - A general term expressing the slippery feel of a lubricant when rubbed with the fingers. *Note:* It is recommended that this term not be used in English (Ref 1).
- **uniformly distributed impact test**
  - See distributed impact test .
- **unlubricated sliding**
  - Sliding without lubricant but not necessarily under completely dry conditions (Ref 1). *Note:* Unlubricated sliding is often used to mean "not intentionally lubricated," but surface species such as naturally formed surface oxides and other interfacial contaminants may act in a lubricious manner in nominally unlubricated sliding.
- **V**
- **V-ring seal**
  - A seal consisting of a ring or nested rings that have a V-shaped cross section and that are commonly made from elastomeric material. *Note:* Spring loading is sometimes used to maintain contact between the seal and its mating surface. It is normally used to seal against axial motion (Ref 4m).
- **vacuum residue**
  - The residue from vacuum distillation of crude oil (Ref 1).
- **vapor-phase lubrication**
  - A type of lubrication in which one or more gaseous reactants are supplied to the vicinity of the surface to be lubricated and which subsequently react to form a lubricious deposit on that surface.

Note: The surface to be lubricated may exhibit a catalytic effect to permit formation of the lubricating film.

- **varnish**
  - In lubrication, a deposit resulting from the oxidation and/or polymerization of fuels, lubricating oils, or organic constituents of bearing materials. *Note:* Harder deposits are described as lacquers, softer deposits are described as gums (Ref 1).
- **VI improver**
  - An additive, usually a polymer, that reduces the variation of viscosity with temperature, thereby increasing the viscosity index of an oil (Ref 1).
- **vibratory cavitation**
  - Cavitation caused by the pressure fluctuations within a liquid, induced by the vibration of a solid surface immersed in the liquid (Ref 2).
- **Vickers (microindentation) hardness number**
  - The numerical value of microindentation hardness obtained using the Vickers (diamond) indenter and calculated as follows:

$$HV_P = 18.192\left[\frac{P}{0.5\,(d_1 + d_2)}\right]$$

  - where HV_P (in units of GPa) is the ASTM symbol indicating Vickers microindentation hardness, *P* is the applied load (in grams), and d_1 and d_2 are the two diagonal lengths of the impression (in μm). *Notes:* To obtain the HV_P in kg/mm^2, as was customary in the past, the factor 18.192 is replaced with 1854.4. The Vickers microindentation hardness test is described in ASTM E 384. A higher-load, macro-Vickers test has also been developed.
- **viscoelasticity**
  - A combination of viscous and elastic properties that makes the deformation dependent upon both temperature and strain rate (Ref 1).
- **viscosity**
  - The bulk property of a fluid, semifluid, or semisolid substance that causes it to resist flow. *Notes:* Viscosity is defined by the equation:

$$\eta = \frac{\tau}{(dv/ds)}$$

  - where τ is the shear stress, *v* is the velocity, and *s* is the thickness of an element measured perpendicular to the direction of flow; (*dv*/*ds*) is known as the rate of shear. Newtonian viscosity is often called dynamic viscosity, or absolute viscosity. Kinematic viscosity, or static viscosity (v) is the ratio of dynamic viscosity (η) to density (ρ) at a specified temperature and pressure ($v = \eta/\rho$). It is recommended that the term static viscosity should not be used (Ref 1m).
- **viscosity, units of**
  - For absolute viscosity, the centimeter-gram-second (cgs) unit is the poise (dyne · s/cm^2), the meter-kilogram-second (mks) unit is the Poiseuille (newton · s/m^2), which is equal to the Système International d'Unités (SI) unit (1.0 N · sm^{-1} = 10 poise), and the English unit is the Reyn (lb · s/in.^{2}), which is not commonly used. For kinematic viscosity, the cgs unit is the Stoke (cm^2/s), the SI unit is m^2 · s^{-1} (1.0 m^2 · s^{-1} = 10^6 centistokes), and the English unit is the Newt (in.^{2}/s), which is not commonly used (Ref 1m).
- **viscosity index (VI)**
  - A commonly used measure of the change in viscosity of a fluid with temperature. *Notes:* The higher the viscosity index, the smaller the relative change in viscosity with temperature. Two different indices are used: The earlier usage, according to Dean and Davis, applies to oils having a VI from 0 to 100. Extended VI applies to oils having a VI of at least 100. It compares the oil with a reference oil of VI 100 (Ref 1m).
- **viscous**
  - Possessing viscosity. *Note:* This term is frequently used to imply high viscosity (Ref 1).

- **viscous friction**
  - See fluid friction .
- **W**
- **wear**
  - (1) Damage to a solid surface, generally involving progressive loss of material, that is due to relative motion between that surface and a contacting substance or substances (Ref 2). (2) The progressive loss of substance from the operating surface of a body occurring as a result of relative motion at the surface (Ref 1). *Note:* The first definition would not necessarily exclude scuffing or galling , in which surface material may be displaced but not removed; however, the second definition requires substance to be removed in order to be considered wear. Sometimes surface damage , which may not involve material removal, is differentiated from wear as defined under the first definition. This Handbook treats wear and surface damage individually.
- **wear coefficient**
  - In sliding wear, a dimensionless number that usually represents the proportionality factor *k* in the Archard wear law . *Note:* The term wear coefficient has been used in other ways than that given in this definition, and when encountered, it is best to verify its meaning from context.
- **wear constant**
  - A term sometimes used interchangeably with the term wear coefficient ; however, it should not be used because wear rate is often not constant under different sliding conditions, and, therefore, the term is misleading.
- **wear debris**
  - Particles that become detached in a wear process (Ref 1m).
- **wear factor**
  - A term that has no unique meaning. When encountered, the meaning of this term must be taken from its immediate context. Sometimes, the term is used to refer to the sliding wear rate in terms of $mm^3 N \cdot m$. See also specific wear rate .
- **wear rate**
  - There is no single, standard way to express wear rate. The units used depend on the type of wear and the nature of the tribosystem in which wear occurs. Wear rate can be expressed, for example, as (1) volume of material removed per unit time, per unit sliding distance, per revolution of a component or per oscillation of a body (that is, in sliding wear), (2) volume loss per unit normal force per unit sliding distance (mm^3/N m, which is sometimes called the wear factor), (3) mass loss per unit time, (4) change in a certain dimension per unit time, and (5) relative change in dimension or volume with respect to the same changes in another (reference) substance. The manner of expressing wear rate is sometimes prescribed in specific standard test methods. In other cases, standards are established for given sectors of technology (for example, mechanical face seal technology). See the sections on specific wear types in this Handbook for more information.
- **wear rate (of seals)**
  - The amount of seal-surface wear, stated in terms of mils worn in some designated time period. *Note:* One commonly used unit is mils per hundred hours (Ref 4m).
- **wear resistance**
  - The resistance of a body to removal of material by wear processes, expressed as the reciprocal of wear rate. *Notes:* Wear resistance is a function of the conditions under which the wear process takes place. These conditions should always be carefully specified. Relative wear resistance is sometimes quoted, using arbitrary standards (Ref 1m).
- **wear scar**
  - The portion of a solid surface that exhibits evidence that material has been removed from it due to the influence of one or more wear processes.
- **wear transition**
  - Any change in the wear rate or in the dominant wear process occurring at a solid surface. *Note:* Wear transitions can be produced by an external change in the applied conditions (for example, load, velocity, temperature, or gaseous environment) or by time-dependent changes (aging) of the materials and restraining fixtures in the tribosystem.
- **wedge effect**
  - The establishment of a pressure wedge in a lubricant (Ref 1). See also wedge formation (2).
- **wedge formation**

- (1) In sliding metals, the formation of a wedge or wedges of plastically sheared metal in local regions of interaction between sliding surfaces. *Note:* This type of wedge is also known as a prow. It is similar to a built-up edge (Ref 1). (2) In hydrodynamic lubrication, the establishment of a pressure gradient in a fluid flowing into a converging channel. *Note:* This is also known as wedge effect (Ref 1).

- **weepage**
  - A minute amount of liquid leakage by a seal. *Note:* It has rather arbitrary limits, but is commonly considered to be a leakage rate of less than one drop of liquid per minute (Ref 4m).
- **welding**
  - In tribology, adhesion between solid surfaces in direct contact at any temperature (Ref 1).
- **whirl (oil)**
  - Instability of a rotating shaft associated with instability in the fluid film (Ref 1).
- **white layer**
  - In tribology, a white-etching layer, typically associated with ferrous alloys, that is visible in metallographic cross sections of bearing surfaces. *Note:* Some interpretations of white layers involve the presence of amorphous material; however, in other cases, the layer is thought to be finely microcrystalline such that no structure is visible by optical microscopy. See also Beilby layer and highly deformed layer .
- **white metal (whitemetal)**
  - A light-colored bearing alloy based on tin or lead. *Note:* Babbitt metal is one of the white metals (Ref 1).
- **wick lubrication**
  - A system in which the lubricant is delivered to the bearing surface by means of a wick (Ref 1).
- **wiper**
  - A pad of felt or other material used to supply lubricant or to remove debris (Ref 1).
- **wiping**
  - In tribology, the smearing or removal of material from one point, often followed by the redeposition of the material at another point, on the surface of two bodies in sliding contact. *Note:* The smeared metal is usually softened or melted (Ref 1).
- **work factor**
  - A measure of the stability of a lubricant when subjected to an endurance test. *Note:* The work factor is expressed as the average value of the ratio of three characteristics (viscosity, carbon residue, and neutralization number) as measured before the test to those same characteristics as measured after the test (Ref 5).
- **wrapped bush (bearing)**
  - A thin-walled steel bush lined with a bearing alloy, or any other bearing bush made from strip (Ref 1).
- **wrist pin bearing**
  - The bearing at the crankshaft end of an articulated connecting rod in a "V" engine (Ref 1).

Abbreviations, Symbols, and Tradenames

Abbreviations and Symbols

- ***a***
  - contact radius for circular contact; semimajor axis of elliptical contact area; area
- a_1
  - life adjustment factor for reliability; reliability factor for other than 90% reliability; reliability factor to adjust the L_{10} life
- a_2
  - life adjustment factor for special bearing properties; material factor for other than standard bearing steels
- a_3
  - application or environmental factor, primarily recognizing the lubricant condition within a bearing (can also include alignment, internal load distribution changes, temperature, contaminants [liquid and solid], and fatigue spall criteria); life adjustment factor for operating conditions
- **A**
  - austenite; ampere; air
- ***A***
  - cross-sectional area; contact area; projected area; solid material
- Å
  - angstrom
- A_1
  - cross-sectional area of a scratch
- **AA**
  - arithmetic roughness; atomic absorption; Aluminum Association
- **ABS**
  - acrylonitrile butadiene styrene
- A_c
  - contact area
- **ac**
  - alternating current
- **AC**
  - air cool
- Ac_1
  - temperature at which austenite begins to form during heating
- Ac_3
  - temperature at which transformation of ferrite to austenite is completed during heating

- **Ac_{cm}**
  - in hypereutectoid steel, temperature at which cementite completes solution in austenite
- **ACF**
  - autocorrelation function
- **A_D**
  - cross-sectional area of displaced material
- **A_e**
  - surface area
- **Ae_{cm},Ae_1, Ae_3**
  - equilibrium transformation temperatures in steel
- **AEF**
  - average energy flux
- **AEM**
  - analytical electron microscope/microscopy
- **AES**
  - Auger electron spectroscopy; acoustic emission spectroscopy
- **AFM**
  - atomic force microscope
- **AG**
  - aged; alternating grinding
- **AGMA**
  - American Gear Manufacturers Association
- **AGR**
  - advanced gas-cooled reactor
- **AISI**
  - American Iron and Steel Institute
- **A_{LB}**
  - load-bearing area (that is, vertical projection of the contact area)
- **alcop**
  - aluminum-copper bronze
- **Ams**
  - Amsler circumferential, rotating disk-on-disk machine
- **AMS**
  - Aerospace Material Specification; acoustic material signature
- **A_N**
  - nominal area of contact
- **AN**
  - annealed
- **ANSI**
  - American National Standards Institute
- **A_p**
  - cross-sectional area of a groove
- **API**
  - American Petroleum Institute
- **A_r**
  - real area of contact; cross-sectional area of formed ridges
- **AR**
  - abrasion resistant
- **Ar_1**
  - temperature at which transformation to ferrite or to ferrite plus cementite is completed on cooling
- **Ar_3**
  - temperature at which transformation of austenite to ferrite begins on cooling
- **Ar_{cm}**
  - temperature at which cementite begins to precipitate from austenite on cooling
- **ARE**
  - activated reactive evaporation
- **ARP**

    - Aerospace Recommended Practice
- **ASLE**
    - American Society of Lubrication Engineers (former name of STLE)
- **ASME**
    - American Society of Mechanical Engineers
- **ASTM**
    - American Society for Testing and Materials
- **at.%**
    - atomic percent
- **ATF**
    - automatic transmission fluid
- **atm**
    - atmospheres (pressure)
- A_w
    - cross-sectional area of the removed material
- **AWL**
    - Archard wear law
- **AWN**
    - antiwear number
- **AWS**
    - American Welding Society
- AX
    - gaseous compound
- b
    - journal bearing width; groove width; semi-minor axis of elliptical contact area
- b_1
    - thermal contact coefficient of body 1
- b_2
    - thermal contact coefficient of body 2
- **B**
    - bainite
- B
    - gaseous reaction product
- B_{10} **life**
    - bearing life
- **bal**
    - balance
- **BAM**
    - Bundesanstalt für Materialforschung und -Prufung
- **BARE**
    - biased activated reactive evaporation
- **bcc**
    - body-centered cubic
- **bct**
    - body-centered tetragonal
- **BEP**
    - best efficiency point (pump flow rate)
- b_f
    - thermal contact coefficient of film
- b_H
    - semiwidth of Hertzian contact band
- b_m
    - rating factor for contemporary, normally used material and manufacturing quality, the value of which varies with bearing type and design
- B_M
    - thermal contact coefficient
- **BOR**

- flat block pressed against the cylindrical surface of a rotating ring

- b_s
  - thermal contact coefficient of a substrate
- **BUE**
  - built-up edge
- c
  - edge length in crystal structure; speed of light; specific heat; constant; bearing radial clearance; conductivity
- **C**
  - cementite; coulomb; heat capacity
- C
  - constant; velocity of light; bearing capacity; shock wave velocity
- C_0
  - acoustic velocity
- C_a
  - basic radial load rating for thrust ball bearings
- **CAD/CAM**
  - computer-aided design/computer-aided manufacturing
- **CAE**
  - corrosion-affected erosion
- **CANMET**
  - Canada Center for Mineral and Energy Technology
- **CBED**
  - convergent-beam electron diffraction
- **CBN**
  - cubic boron nitride
- **CCT**
  - continuous-cooling transformation
- **CCVD**
  - conventional chemical vapor deposition
- c_d
  - diametrical clearance
- **cd**
  - candela
- **CE**
  - carbon equivalent
- C_f
  - bearing friction factor
- **CFG**
  - creep feed grinding
- **cgs**
  - centimeter-gram-second (system of units)
- **CI**
  - compression ignition
- **CLA**
  - center-line average
- c_M
  - specific heat per unit mass
- **cm**
  - centimeter
- **CMA**
  - cylindrical mirror analyzer
- **CNC**
  - computer numerical control
- C_{oa}
  - basic static axial load rating
- C_{or}

- basic static radial load rating
- **c_p**
  - specific heat at constant pressure
- **cP**
  - centipoise
- **CPI**
  - chemical process industry
- **c_r**
  - radial clearance
- **C_r**
  - basic radial load rating
- **C_R**
  - basic radial dynamic capacity based on the equations

  - coefficient of thermal expansion
- **CTEM**
  - conventional transmission electron microscope/microscopy
- **CVD**
  - chemical vapor deposition
- **CVI**
  - chemical vapor infiltration
- **CVM**
  - consumable vacuum-melted
- **CVN**
  - Charpy V-notch (impact test or specimen)
- **cw**
  - continuous wave
- **d**
  - day
- ***d***
  - used in mathematical expressions involving a derivative (denotes rate of change); depth; diameter
- **D**
  - die cast
- ***D***
  - diameter; penetration depth
- ***d****
  - average value of two diagonals in Vickers indenter
- ***da/dN***
  - fatigue crack growth rate
- **DAT**
  - digital audio tape
- **d_B**
  - diameter of Brinell hardness indentation
- **dB**
  - decibel
- **D_B**
  - ball diameter of Brinell hardness tester

- **DBT**
  - ductile-to-brittle transition
- **dc**
  - direct current
- d_f
  - length of hardness indentation diagonal after wear occurs
- D_f
  - thermal diffusivity of lubricant film
- dF_N/dt
  - loading rate
- **dhcp**
  - double hexagonal close-packed
- D_i
  - thermal diffusivity of body i
- **diam**
  - diameter
- **DIN**
  - Deutsche Industrie-Normen (German Industrial Standards)
- **DLC**
  - diamondlike carbon
- dL/dX
  - loading rate
- $DN_e/A_e dt$
  - number of molecules evaporating from a surface area A_e in time dt
- d_o
  - diameter resulting from elastic deformation; width of diameter of area supporting a load before wear (that is, Hertz width); elastic contact diameter; length of the diagonal of a hardness indentation before wear occurs
- **dpa**
  - displacements per incident atom
- **DPH**
  - diamond pyramid hardness
- d_{v1}
  - one of two diagonals in Vickers indenter
- d_{v2}
  - one of two diagonals in Vickers indenter
- dx/dt
  - scratching speed
- e
  - natural log base, 2.71828; charge of an electron; specific grooving energy
- E
  - erosion rate; Young's modulus; modulus of elasticity; applied voltage; energy; activation energy
- E_1
  - modulus of elasticity of a pinion
- E_2
  - modulus of elasticity of a gear
- **EAP**
  - end of active profile
- **EAW**
  - electric arc wire (spray)
- e_B
  - maximum height of asperities on a bearing
- **EB**
  - electron beam
- E_c
  - Young's modulus of a coating
- **E/C**

- erosion/corrosion
- **ECP**
  - electron channeling pattern
- $\boldsymbol{E}_{\mathbf{d}}$
  - displacement energy
- **EDM**
  - electrical discharge machining
- **EDS**
  - energy-dispersive spectrometer
- **EDX**
  - energy-dispersive spectroscopy
- **EDXA**
  - energy-dispersive x-ray analysis
- **EEC**
  - erosion-enhanced corrosion
- **EELS**
  - electron energy loss spectroscopy
- **EHD**
  - elastohydrodynamic
- **EHL**
  - elastohydrodynamic lubrication
- $\boldsymbol{E}_{\mathbf{i}}$
  - kinetic energy of an incident ion
- ***EI***
  - flexural rigidity
- **ELI**
  - extra-low interstitial
- **ELNES**
  - energy-loss near-edge structure
- **emf**
  - electromotive force
- **EP**
  - extreme pressure
- **EPA**
  - Environmental Protection Agency
- **EPMA**
  - electron probe microanalysis
- **Eq**
  - equation
- $\boldsymbol{E}_{\mathbf{r}}$
  - reduced modulus of elasticity
- $\boldsymbol{e}_{\mathbf{s}}$
  - maximum height of asperities on a bearing shaft
- **ESCA**
  - electron spectroscopy for chemical analysis
- **ESD**
  - electrospark deposition; electron-stimulated desorption
- **ESDIED**
  - electron-stimulated desorption-ion energy distribution
- **ESR**
  - electroslag remelting
- ***et al.***
  - and others
- **eV**
  - electron volt
- **exp**
  - base of the natural logarithm

- ***f***
  - frequency; transfer; minimum facet contact area fraction; ratio of raceway curvature radius to ball diameter; friction coefficient; volume fraction
- $\boldsymbol{f_1}$
  - factor depending on bearing design and load
- **F**
  - ferrite
- ***F***
  - face width of line contact in direction perpendicular to rolling; bushing length; coefficient dependent on the form of the heat flux distribution; friction force; load; force
- $\mathbf{F_o}$
  - Fourier modulus
- $\boldsymbol{F_a}$
  - applied thrust load
- $\boldsymbol{F_A}$
  - adhesive friction force
- **FAA**
  - Federal Aviation Administration
- $\boldsymbol{f_{ab}}$
  - removal coefficient
- **FBC**
  - fluidized bed combustion
- $\boldsymbol{f_c}$
  - volume fraction of coating material being deformed; factor that depends on the composition of the material geometry of bearing components and the accuracy to which the various components are made
- **fcc**
  - face-centered cubic
- **fct**
  - face-centered tetragonal
- **FEA**
  - finite element analysis
- $\boldsymbol{F_F}$
  - frictional force
- **FFT**
  - fast Fourier transform
- **Fig**
  - figure
- $\boldsymbol{F_N}$
  - applied (normal) load
- **FOF**
  - flat surface sliding on another flat surface
- $\boldsymbol{F_P}$
  - plowing component of friction
- $\boldsymbol{F_r}$
  - applied radial load
- $\boldsymbol{f_s}$
  - volume fraction of substrate material being deformed
- **FSZ**
  - fully stabilized zirconia
- **ft**
  - foot
- $\boldsymbol{F_T}$
  - tangential force
- **FTIR**
  - Fourier transform infrared spectroscopy
- $\boldsymbol{f_v}$

    - constant dependent on bearing type and lubrication
- **FZG**
    - Forschungsstelle für Zahnräder und Getriebebau (Technical Institute for the Study of Gears and Drive Mechanisms)
- $F\beta$
    - applicable load
- **g**
    - gram
- ***g***
    - acceleration due to gravity
- **G**
    - graphite; gauss
- ***G***
    - dimensionless material parameter
- $G\chi$
    - limiting shear modulus
- **gal**
    - gallon
- **gf**
    - gram force
- G_{Ic}
    - critical strain energy release rate
- **GPa**
    - gigapascal
- **GTA**
    - gas tungsten arc
- **h**
    - hour; vertical thickness; minimum lubricant film thickness; bearing film thickness; depth of wear; Planck's constant. (6.626×10^{-27} erg · s)
- $\bar{h}$
    - average lubricant film thickness
- ***h****
    - asperity film thickness or micro-elastohydrodynamic film thickness
- h_0
    - inlet film thickness
- **H**
    - Henry
- ***H***
    - enthalpy; hardness; magnetic field; height; depth of wear; power loss
- H_a
    - allowable depth of wear
- **HAIM**
    - high-frequency acoustic imaging
- **HAZ**
    - heat-affected zone
- **HB**
    - Brinell hardness
- H_c
    - coating hardness; composite hardness
- **hcp**
    - hexagonal close-packed
- H_{comp}
    - effective hardness number
- H_{def}
    - hardness of highly deformed structure
- **HDPE**

    - high-density polyethylene
- **h_e**
    - depth of wear with elastic springback
- **HERF**
    - high-energy-rate forming
- **H_f**
    - hardness of film
- **HIP**
    - hot isostatic pressing
- **HK**
    - Knoop hardness
- **HLB**
    - hydrophile-lipophile balance
- **h_{min}**
    - minimum oil film thickness
- **HMX**
    - cyclotetramethylene tetranitramine
- **HOPG**
    - highly oriented pyrolytic graphite
- **hp**
    - horsepower
- **HP**
    - high-purity; hot pressed
- **H_P**
    - plowing stress
- **HPC**
    - high-pressure compressor
- **HPSTC**
    - highest point of single tooth contact
- **HPT**
    - high-pressure turbine
- **HR**
    - Rockwell hardness (Requires scale designation, such as HRC for Rockwell C hardness)
- **HREM**
    - high-resolution electron microscopy (microhardness)
- **HRMF**
    - Rockwell microficial (microhardness)
- **H_s**
    - substrate hardness

  - transmitted electron current
- **J**
  - joule
- ***J***
  - ion current density
- $\boldsymbol{J}_{\mathbf{eq}}$
  - Jominy equivalent
- **k**
  - Boltzmann constant
- ***k***
  - thermal conductivity; Boltzmann constant; wear factor; wear coefficient
- **K**
  - Kelvin
- ***K***
  - wear coefficient; specific wear rate
- **kg**

- kilogram
- **kgf**
  - kilogram force
- K_{Ic}
  - plane-strain fracture toughness
- K_{ISCC}
  - threshold stress intensity to produce stress-corrosion cracking
- **km**
  - kilometer
- **kN**
  - kilonewton
- **kPa**
  - kilopascal
- k_s
  - specific cutting force
- **ksi**
  - kips (1000 lbf) per square inch
- **kV**
  - kilovolt
- **kW**
  - kilowatt
- l
  - length
- ℓ
  - length
- ℓ_0
  - length of asperity
- **L**
  - longitudinal, liter
- L
  - relative bearing life; length of bearing (land) of a die; contact length
- L_{10}
  - fatigue life that 90% of a group of bearings will endure; bearing life for 90% reliability
- L_{50}
  - median bearing life
- **lb**
  - pound
- **lbf**
  - pound force
- L_c
  - characteristic length
- **LCVD**
  - laser-induced chemical vapor deposition
- **LCL**
  - lower control limit
- **LCP**
  - liquid crystal polymer
- **LCSM**
  - laser confocal scanning microscope
- **LDPE**
  - low-density polyethylene
- L_{min}
  - minimum contact length
- **In**
  - natural logarithm (base *e*)
- L_{na}

- calculated life adjusted by the multiplicative factors a_1, a_2, and a_3 (in rev); the bearing life in millions of revolutions (na × 10^6

- **log**
  - common logarithm (base 10)
- **LPCVD**
  - low-pressure chemical vapor deposition
- **LPG**
  - liquified petroleum gas
- **LPSTC**
  - lowest point of single tooth contact
- **LPT**
  - low-pressure turbine
- **L_R**
  - bearing life in terms of ratio to catalog expected life (that is, relative fatigue life)
- **LSI**
  - large-scale integrated (circuit)
- **LT**
  - long transverse (direction)
- **LVDT**
  - linear variable differential transformer
- **m**
  - meter
- ***m***
  - constant shear, or frictional factor, Weibull slope, for reliability above 90%; Weibull distribution; dispersion parameter; molecular weight
- ***M***
  - bearing total friction torque
- **M_1**
  - bearing friction torque due to rolling element-raceway contact loading
- **mA**
  - milliampere
- **M_A**
  - atomic weight of target material
- **MAS**
  - Microbeam Analysis Society
- **MCD**
  - magnetic chip detection
- **MEP**
  - mean effective pressure
- **MeV**
  - megaelectronvolt
- **M_f**
  - temperature at which martensite formation finishes during cooling
- **MFP**
  - mean free path
- **mg**
  - milligram
- **Mg**
  - megagram (metric tonne, or kg × 10_3)
- **min**
  - minute; minimum
- **M_i**
  - mass of the incident atom
- **MIG**
  - metal inert gas (welding)
- **MIR**
  - multiple internal reflectance

- **mL**
  - milliliter
- **mm**
  - millimeter
- **MMC**
  - metal-matrix composite
- **MOCVD**
  - metal-organic chemical vapor deposition
- **mPa**
  - millipascal
- **MPa**
  - megapascal
- **mpg**
  - miles per gallon
- **mph**
  - miles per hour
- **MRR**
  - material removal rate
- **ms**
  - millisecond
- **M_s**
  - temperature at which martensite starts to form from austenite on cooling
- **MS**
  - megasiemens; magnetron sputtering
- **MSA**
  - Microscopy Society of America
- **MSDS**
  - material safety data sheet
- **mT**
  - millitesla
- **M_t**
  - mass of the target atom
- **MTTF**
  - mean time to failure
- **mV**
  - millivolt
- **MV**
  - megavolt
- **M_v**
  - bearing friction torque due to hydrodynamic fluid friction
- ***n***
  - pinion speed; load life exponent (experimentally based, with consensus values published in the bearing standards; typically, n = 3 for ball bearings and n = 10/3 for roller bearings); number of triangles in regular polygon; independent contact points conducting in parallel; bearing speed
- **N**
  - newton
- ***N***
  - number of cycles; normal solution; angular velocity of cylindrical contact; bearing speed; normal force
- **NA**
  - numerical aperture
- **NASA**
  - National Aeronautics and Space Administration
- **NBS**
  - National Bureau of Standards (former name of NIST)
- **NDE**
  - nondestructive evaluation

- **NER**
  - erosion resistance number
- n_i
  - inner ring speed
- **NIST**
  - National Institute of Standards and Technology
- **nm**
  - nanometer
- n_m
  - cage speed (rolling-element orbital speed)
- **NMMA**
  - National Marine Manufacturers Association
- n_o
  - outer ring speed
- **No.**
  - number
- N_0
  - rationalized incubation period
- ***NOR***
  - incubation resistance number
- **NPSH**
  - net positive suction head
- **NPSHA**
  - available net positive suction head
- **NPSHR**
  - required net positive suction head
- n_{RE}
  - ball or roller speed about its own axis
- **ns**
  - nanosecond
- **NSp**
  - not specified
- $N(\Lambda)/N_{cat}$
  - relative life factor
- $N_{\mu e=0}$
  - fatigue life when surface traction equals zero
- **Oe**
  - oersted
- **OECD**
  - Organisation for Economic Cooperation and Development
- **OFD**
  - oxyfuel detonation (spray)
- **OFP**
  - oxyfuel powder (spray)
- **OFW**
  - oxyfuel wire (spray)
- **OMCVD**
  - organo-metallic chemical vapor deposition
- **ORNL**
  - Oak Ridge National Laboratory
- **OSHA**
  - Occupational Safety and Health Administration
- **oz**
  - ounce
- **p**
  - page

- ***p***
  - pressure; hydrostatic pressure acting on the surface
- ***p****
  - local asperity contact pressure; equilibrium vapor pressure at an evaporant surface
- $\bar{p}$
  - average (bulk) hydrodynamic pressure
- **P**
  - pearlite
- ***P***
  - specific load or unit load; pressure; transmitted power
- P_a
  - absolute ambient pressure
- $\bar{p}_a$
  - average (bulk) asperity contact pressure
- **Pa**
  - pascal
- **PA**
  - plasma arc (spray); prealloyed; polyamide
- **PACVD**
  - plasma-assisted chemical vapor deposition
- **PAN**
  - polyacrylonitrile
- **PAO**
  - polyalphaolefin
- **PAPVD**
  - plasma-assisted physical vapor deposition
- **PBT**
  - polybutylene terephthalate
- **PCD**
  - polycrystalline diamond
- **PCV**
  - positive crankcase ventilator
- **PDF**
  - probability density function
- **Pe**
  - Péclet number
- **PEEK**
  - polyetheretherketone
- **PEI**
  - polyetherimide
- **PEK**
  - polyetherketone
- **PEP**
  - passive extreme pressure
- **PES**
  - polyether sulfone
- **PETN**
  - pentaerithritol tetranitrate
- **PETP**
  - polyethylene terephthalate
- **PFPE**
  - polyperfluoroalkylether
- **pH**
  - negative logarithm of hydrogen-ion activity
- p_H
  - maximum Hertzian contact pressure
- **PH**

- precipitation hardenable
- **P_H**
  - hardness; Brinell pressure
- **PHL**
  - plastohydrodynamic lubrication
- **p_i**
  - pocket pressure in hydrostatic bearing
- **PKA**
  - primary knock-on atom
- **PLP**
  - percent of large particles
- **p_m**
  - flow pressure or hardness of material
- **PM**
  - permanent mold
- **P/M**
  - powder metallurgy
- **PMMA**
  - polymethyl methacrylate
- **P_N**
  - nominal normal stress on contact patch
- **p_o**
  - yield pressure
- **POD**
  - pin on disk
- **POF**
  - pin on flat
- **POM**
  - polyoxymethylene
- **P_{or}**
  - static equivalent radial load
- **POR**
  - pin sliding against the cylindrical surface of a rotating ring
- **ppb**
  - parts per billion
- **ppba**
  - parts per billion atomic
- **ppm**
  - parts per million
- **ppmm**
  - parts per million by mass
- **PPS**
  - polyphenylene sulfide
- **ppt**
  - parts per trillion
- **PSD**
  - power spectral density
- **psi**
  - pounds per square inch
- **psia**
  - pounds per square inch absolute
- **psig**
  - gage pressure (pressure relative to ambient pressure) in pounds per square inch
- **PSII**
  - plasma-source ion implantation
- **PSZ**
  - partially stabilized zirconia

- **PTA**
  - plasma transferred arc
- **PTFE**
  - polytetrafluoroethylene
- P_u
  - fatigue load limit
- **PVC**
  - polyvinyl chloride
- **PVD**
  - physical vapor deposition
- **PVDF**
  - polyvinylidene-difluoride
- q
  - heat flux distribution; oil flow rate
- Q
  - thermal energy generated per unit time
- q_{av}
  - average heat flux distribution
- $\overline{Q}_e$
  - contact stress
- Q_{gen}
  - heat generation
- Q_i
  - rate of heat supplied to body i
- r
  - radius; radial distance of receiver from source; resistivity
- **R**
  - roentgen
- R
  - radius; gas constant; reliability expressed in terms of percent survival; resistance
- **R**
  - force vector
- r_o
  - relative radius at an area before wear
- R_o
  - surface radius with lubricant film
- r_1
  - radius of surface 1 at area before wear
- r_2
  - radius of surface 2 at area before wear
- r_I
  - radius of rolling body I
- r_{II}
  - radius of rolling body II
- R_a
  - surface roughness in terms of arithmetic average
- ***RA***
  - reduction in area
- r^{β}
  - bushing radius
- **RB**
  - reaction bonded
- **RCF**
  - rolling contact fatigue
- **RCW**
  - rolling contact wear

- **RDX**
  - cyclotrimethylene trinitramine
- $\boldsymbol{R}_{\mathbf{e}}$
  - equivalent radius of curvature; rationed erosion rate
- **RE**
  - rare earth
- **Ref**
  - reference
- **REF**
  - relative erosion factor
- **rf**
  - radio frequency
- **RH**
  - relative humidity
- **RIP**
  - reactive ion plating
- **rms**
  - root mean square
- $\boldsymbol{R}_{\mathbf{n}}$
  - neutral radius
- $\boldsymbol{R}_{\mathbf{p}}$
  - single predominant peak height; leveling depth
- **rpm**
  - revolutions per minute
- $\boldsymbol{R}_{\mathbf{pm}}$
  - mean height of highest peaks on five adjacent sampling lengths; average leveling depth
- **RPOF**
  - reciprocating pin on flat
- $\boldsymbol{R}_{\mathbf{q}}$
  - rms (root means square) roughness
- **R & O**
  - rust and oxidation inhibited
- $\boldsymbol{r}_{\mathbf{s}}$
  - shaft radius
- **RS**
  - reactive sputtering
- $\boldsymbol{R}_{\mathbf{sk}}$
  - skew roughness
- **RSOF**
  - reciprocating, spherically ended pin on a flat surface
- **RT**
  - room temperature
- **RTD**
  - resistance temperature detector
- **RTO**
  - rejected take-off
- **RTV**
  - room-temperature vulcanizing
- **RWAT**
  - rubber wheel abrasion test
- $\boldsymbol{R}_{\mathbf{y}}$
  - maximum peak-to-valley height
- $\boldsymbol{R}_{\mathbf{z}}$
  - ten-point height
- **s**
  - second
- $\boldsymbol{s}$

    - standard deviation
- **S**
    - sand cast; siemens
- ***S***
    - sputtering yield; Sommerfeld number; rotational speed; rms average surface roughness; probability of survival
- **SAD**
    - selected-area diffraction
- **SAE**
    - Society of Automotive Engineers
- **SAG**
    - semiautogenous
- **SAM**
    - scanning acoustic microscope/microscopy
- **SAP**
    - sintered aluminum powder; start of active profile
- **SAR**
    - slurry abrasion response (number)
- **SAW**
    - surface acoustic wave
- **SCaM**
    - scanning capacitance microscope
- **SCC**
    - stress-corrosion cracking
- **SEM**
    - scanning electron microscope/microscopy
- **SF**
    - segregation factor
- **SFA**
    - surface force apparatus
- **sfm**
    - surface feet per minute
- **SHC**
    - synthetic hydrocarbon
- **SHE**
    - standard hydrogen electrode
- **SI**
    - spark ignition; Système International d'Unités
- **SIMS**
    - secondary ion mass spectroscopy
- **Si/SiC**
    - silicon-infiltrated silicon carbide
- **SKA**
    - secondary knock-on atom
- **SLA**
    - surface layer activation
- **SLAM**
    - scanning laser acoustic microscope/microscopy
- **SMA**
    - shielded metal arc
- **SMAW**
    - shielded metal arc welding
- **SMD**
    - Sauter mean diameter
- **SNR**
    - signal-to-noise ratio
- **SOAP**

- spectrometric oil analysis program

- **SPC**
  - statistical process control
- **SPE**
  - solid particle erosion
- **SPOD**
  - spherically ended pin on flat disk
- **SPOF**
  - spherically ended pin on flat coupon
- **SPP**
  - second-phase particle
- **SPVF**
  - second-phase (particle) volume fraction
- **SQC**
  - statistical quality control
- **SRF**
  - strength reduction factor
- **SRM**
  - Standard Reference Materials
- **SRP**
  - self-reinforcing polymer
- **ST**
  - short transverse (direction)
- **STA**
  - solution-treated and aged
- **std**
  - standard
- **STEM**
  - scanning transmission electron microscope/microscopy
- **STLE**
  - Society of Tribologists and Lubrication Engineers (formerly ASLE)
- **STM**
  - scanning tunneling microscope/microscopy
- **StOD**
  - strand wrapped over a drum
- S_u
  - ultimate strength
- **SUS**
  - Saybolt Universal Seconds (viscosity)
- **Sv**
  - sievert
- t
  - thickness; time
- **T**
  - tesla
- T
  - temperature; thickness
- **TAN**
  - total acid number
- T_b
  - bulk volumetric temperature; gear bulk temperature (equilibrium temperature of surface of the gear teeth before they enter the meshing zone)
- T_{bi}
  - maximum bulk temperature
- **TBN**
  - total base number
- T_{btest}

- bulk temperature of test gears
- T_c
  - contact temperature; critical temperature; Curie temperature
- $\overline{T}_c$
  - average surface temperature over a given real area of contact
- **TC**
  - test configuration
- **TD**
  - Toyota Diffusion (process)
- T_e
  - electron temperature
- T_E
  - temperature rise of a bearing environment
- **TEI**
  - thermoelastic instability
- **TEM**
  - transmission electron microscope/microscopy
- T_f
  - flash temperature (local and instantaneous temperature rise that occurs on gear teeth as they pass through the meshing zone)
- $\overline{T}_f$
  - average flash temperature
- T_F
  - frictional torque
- T_{fi}
  - maximum flash temperature
- **TFTC**
  - thin-film thermocouple
- T_{ftest}
  - maximum flash temperature of test gears
- T_{fw}
  - surface temperature rise with film
- T_{fwo}
  - surface temperature rise without film
- **TGA**
  - thermogravimetric analysis
- **TGS**
  - threshold galling stress
- **TIG**
  - tungsten inert gas (welding)
- **TLA**
  - thin layer activation
- T_m
  - mean contact temperature; melting temperature
- **TPOD**
  - triple pin-on-disk
- t_r
  - required life
- **TRS**
  - transverse rupture strength
- T_s
  - temperature rise of a bearing surface; scuffing temperature
- **TS**
  - tribosystem
- $\overline{T}_s$
  - average (bulk) surface temperature rise

- $\boldsymbol{T^*_s}$
  - local asperity contact temperature rise
- **tsi**
  - tons per square inch
- **TSM**
  - tandem scanning microscope/microscopy
- **TTT**
  - time-temperature transformation
- **TW**
  - thrust washer test
- $\boldsymbol{u_I}$
  - surface velocity of body I in the rolling direction
- $\boldsymbol{u_{II}}$
  - surface velocity of body II in the rolling direction
- $\boldsymbol{U}$
  - heat of sublimation of target material; dimensionless speed parameter
- $\overline{U}$
  - rolling velocity
- **UCL**
  - upper control limit
- **UHDPE**
  - ultrahigh-density polyethylene
- **UHMWPE**
  - ultrahigh-molecular-weight polyethylene
- **UnSp**
  - unspecified method
- **UHV**
  - ultrahigh vacuum
- **UNS**
  - Unified Numbering System
- **USPHS**
  - United States Public Health Service
- **UTS**
  - ultimate tensile strength
- $\boldsymbol{v}$
  - velocity; particle velocity
- **V**
  - volt
- $\boldsymbol{V}$
  - sliding speed; velocity; volume
- $\boldsymbol{V_1}$
  - velocity of surface 1, which is tangential to contact and normal to contact length
- $\boldsymbol{V_2}$
  - velocity of surface 2, which is tangential to contact and normal to contact length
- **VAMAS**
  - Versailles Advanced Materials and Standards
- **VAR**
  - vacuum arc remelted
- **VCR**
  - video cassette recorder
- $\boldsymbol{V_e}$
  - worn volume with elastic springback; entraining velocity
- **VFD**
  - variable-frequency drive
- **VHN**
  - Vickers microindenter hardness number
- $\boldsymbol{V_i}$

- velocity of body i
- **VI**
  - viscosity index
- **VII**
  - viscosity index improver
- **VIM-VAR**
  - vacuum induction melted-vacuum arc remelted
- **vol**
  - volume
- **vol%**
  - volume percent
- v_{r1}
  - rolling velocity of pinion
- v_{r2}
  - rolling velocity of gear
- v_R
  - Rayleigh velocity
- **VTP**
  - vertical turbine pump
- **VTR**
  - video tape recorder
- w
  - width; mass losses
- **W**
  - watt
- W
  - load; bearing load-carrying parameter; weight of body; abrasive wear resistance; wear volume
- W_{12}
  - work of adhesion
- **WDS**
  - wavelength-dispersive spectrometer
- W_f
  - friction power loss
- $\overline{W}_{Nr}$
  - normal operating load
- **WPC**
  - wear particle concentration
- **WRA**
  - silicon carbide whisker-reinforced alumina
- **WRZTA**
  - silicon carbide whisker-reinforced, zirconia-toughened alumina
- W_s
  - shear power of deformation
- **wt%**
  - weight percent
- X
  - water concentration; interfacial constraint parameter
- **XPS**
  - x-ray photoelectron spectroscopy
- X_Γ
  - load sharing factor
- **XRD**
  - x-ray diffraction
- **XRF**
  - x-ray fluorescence
- **XTEM**
  - cross-sectional transmission electron microscopy

- **X_w**
    - welding factor
- $\bar{y}$
    - mean deviation
- ***Y***
    - yield stress in tension
- **yr**
    - year
- ***z***
    - incremental wear depth
- **z_1**
    - penetration depth
- ***Z***
    - number of rollers carrying load in one direction; number of balls carrying load in one direction; number of balls per row; atomic number
- **ZAP**
    - zone axis pattern
- **ZDDP**
    - zinc dialkyldithiophosphate
- **ZTA**
    - zirconia-toughened alumina
- °
    - angular measure; degree
- **°C**
    - degree Celsius (centigrade)
- **°F**
    - degree Fahrenheit
- $\rightleftarrows$
    - direction of reaction
- ÷
    - divided by
- =
    - equals
- $\approxeq$
    - approximately equals
- $\neq$
    - not equal to
- $\equiv$
    - identical with
- >
    - greater than
- $\gg$
    - much greater than
- $\geq$
    - greater than or equal to
- ∞
    - infinity
- $\propto$
    - is proportional to; varies as
- $\int$
    - integral of
- <
    - less than
- $\ll$
    - much less than
- $\leq$
    - less than or equal to
- ±

- maximum deviation
- -
  - minus; negative ion charge
- ×
  - diameters (magnification); multiplied by
- ·
  - multiplied by
- /
  - per
- %
  - percent
- +
  - plus; positive ion charge
- $\surd$
  - square root of
- $\sim$
  - approximately; similar to
- ∂
  - partial derivative
- α
  - nominal contact angle; semicone angle; thermal diffusivity; taper angle; angle of incidence; radius of clustered contact spots; contact patch radius, pressure-viscosity coefficient
- $\alpha\nu$
  - evaporation coefficient
- β
  - coefficient of friction
- γ
  - surface energy; pressure-viscosity coefficient; heat partition factor
- γ
  - shear strain rate
- γ_1
  - specific surface energy of coating
- γ_2
  - specific surface energy of substrate
- γ_{12}
  - interfacial specific free energy
- Γ^{-1}
  - composite of principal relative curvatures of contacting bodies
- δ
  - film width
- Δ
  - change in quantity; an increment; a range; critical amplitude
- ΔE
  - dissociation energy of gas molecules
- ϵ
  - lubricant film thickness; tribocontact parameter; emissivity; bearing eccentricity ratio; strain
- $\dot{\epsilon}$
  - strain rate
- η
  - lubricant viscosity; efficiency of material removal; degree of wear; abrasive fraction
- η_0
  - absolute viscosity at contact inlet; ambient viscosity of lubricant
- θ
  - angle
- λ
  - wavelength; pressure coefficient of viscosity; film thickness-to-roughness ratio; lambda ratio; specific film thickness
- λ_M

- heat conductivity
- Λ
  - specific film thickness; compressibility number; film thickness parameter
- μ
  - friction coefficient; magnetic permeability; lubricant viscosity at bearing operating temperature; absolute viscosity
- μ_0
  - absolute viscosity
- μ_A
  - adhesional component of the friction coefficient
- μ_e
  - surface traction
- μ_m
  - mean coefficient of friction
- μ_s
  - static coefficient of friction
- μ**F**
  - microfarads
- μ**in.**
  - microinch
- μ**m**
  - micrometer (micron)
- μ**s**
  - microsecond
- ν
  - Poisson's ratio; kinematic viscosity of a lubricant (in cSt) at bearing operating temperature
- ν_c
  - Poisson's ratio of coating material
- ν_1
  - Poisson's ratio of pinion
- ν_2
  - Poisson's ratio of gear
- ν_{40}
  - kinematic viscosity at 40 °C (105 °F)
- ξ
  - Poisson's ratio
- π
  - pi (3.141592)
- ρ
  - density
- ρ_M
  - density
- ρ_n
  - normal relative radius of curvature
- ρ_1
  - transverse radius of curvature of pinion
- ρ_2
  - transverse radius of curvature of gear
- σ
  - workpiece flow strength; stress; standard deviation; root-mean-square roughness; Stefan-Boltzmann constant
- σ_0
  - flow strength
- σ_1
  - rms surface roughness of pinion
- σ_2
  - rms surface roughness of gear

- σ_{max}
  - maximum normal contact stress at center of contact
- σ_s
  - shear stress
- σ_{xb}
  - extrusion pressure (back tension)
- σ_{xf}
  - drawing stress (front tension)
- Σ
  - summation of
- τ
  - applied stress
- $\overline{\tau}$
  - average lubricant shear stress
- τ*
  - local asperity contact shear stress
- τ_L
  - limiting shear stress
- Υ
  - rate of wear
- ϕ
  - standard normal distribution
- Φ
  - energy rate; work function
- Φ_0
  - angular contact width
- Ψ
  - rolling angle
- Ψ_b
  - base helix angle
- ω
  - angular velocity; frequency
- ω_1
  - angular velocity of pinion
- ω_2
  - angular velocity of gear
- ω_{Nr}
  - normal unit load
- Ω
  - ohm
